Abstract
This document provides a definition of a standard Data Format Description Language (DFDL). This language allows description of text, dense binary, and legacy data formats in a vendor-neutral declarative manner. DFDL is an extension to the XML Schema Description Language (XSD).

Example 2
1 Introduction

Data interchange is critically important for most computing. Grid computing, Cloud computing, and all forms of distributed computing require distributed software and hardware resources to work together. Inevitably, these resources read and write data in a variety of formats. General tools for data interchange are essential to solving such problems. Scalable and High-Performance Computing (HPC) applications require high-performance data handling, so data interchange standards must enable efficient representation of data. Data Format Description Language (DFDL) enables powerful data interchange and very high-performance data handling.

One can envisage three dominant kinds of data in the future, as follows:

1. Textual data defined by a format specific schema such as XML [XML] or JSON [JSON].
2. Binary data in standard formats.
3. Data with DFDL descriptors.

Textual XML and JSON data are the most successful data interchange standards to date. All such data are by definition new, meaning created in the Internet era. Because of the large overhead that textual tagging imposes, there is often a need to compress and decompress XML and JSON data. However, there is a high cost for compression and decompression that is unacceptable to some applications. Standardized binary data formats are also relatively new and are suitable for larger data because of the reduced costs of encoding and more compact size. Examples of standard binary formats are data described by modern versions of ASN.1 [ASN1], XDR [XDR], Thrift [Thrift], Avro [AVRO], and Google Protocol Buffers [GPB]. These techniques lack the self-describing nature of XML or JSON data. Scientific formats, such as NetCDF [NetCDF] and HDF [HDF] are used by some communities to provide self-describing binary data. There are also standardized binary-encoded XML data formats such as EXI [EXI].

It is an important observation that both XML format and standardized binary formats are prescriptive in that they specify or prescribe a representation of the data. To use them applications must be written to conform to their encodings and mechanisms of expression.

DFDL suggests an entirely different scheme. The approach is descriptive in that one chooses an appropriate data representation for an application based on its needs and one then describes the format using DFDL so that multiple programs can directly interchange the described data. DFDL descriptions can be provided by the creator of the format or developed as needed by third parties intending to use the format. That is, DFDL is not a format for data; it is a way of describing any data format. DFDL is intended for data commonly found in scientific and numeric computations, as well as record-oriented representations found in commercial data processing.

DFDL can be used to describe legacy data files, to simplify transfer of data across domains without requiring global standard formats, or to allow third-party tools to easily access multiple formats. DFDL can also be a powerful tool for supporting backward compatibility as formats evolve.

DFDL is designed to provide flexibility and permit implementations that achieve very high levels of performance. DFDL descriptions are separable and native applications do not need to use DFDL libraries to parse their data formats. DFDL parsers can also be highly efficient. The DFDL language is designed to permit implementations that use lazy evaluation of formats and to support seekable, random access to data. The following goals can be achieved by DFDL implementations:

- Density. Fewest bytes to represent information (without resorting to compression). Fastest possible I/O.

---

1 ASN.1 with any of the prescribed encoding rules: Basic Encoding Rules (BER), Distinguished Encoding Rules (DER), Canonical Encoding Rules (CER) [ASN1CER] or Packed Encoding Rules (PER) [ASN1PER]
2 Additional examples of descriptive approaches: ASN1 Encoding Control Notation (also known as ITU-T X.692) [ASN1ECN], BFD: Binary Format Description (BFD) Language [BFD]. The largest set of examples of descriptive approaches are all the various proprietary ad-hoc format description languages found almost universally in every commercial database, analytical, or enterprise software system that must take in data.
- Optimized I/O. Applications can write data aligned to byte, word, or even page boundaries and to use memory mapped I/O to ensure access to data with the smallest number of machine cycles for common use cases without sacrificing general access.

DFDL can describe the same types of abstract data that other binary or textual data formats can describe and, furthermore, it can describe almost any possible representation scheme for those data. It is the intent of DFDL to support canonical data descriptions that correspond closely to the original in-memory representation of the data, and to provide sufficient information to write as well as to read the given format.

1.1 Why is DFDL Needed?

In an era when there are so many standard data formats available the question arises of why DFDL is needed. Ultimately, it is because data formats are rarely a primary consideration when programs are initially created.

Programs are very often written speculatively, that is, without any advance understanding of how important they will become. Given this situation, little effort is expended on data formats since it remains easier to program the I/O in the most straightforward way possible with the programming tools in use. Even something as simple as using an XML-based data format is often harder than just using the native I/O libraries of a programming language.

In time, however, if a software program becomes important either because many people are using it, or it has become important for business or organizational needs, it is often too late to go back and change the data formats. For example, there may be real or perceived business costs to delaying the deployment of a program for a rewrite just to change the data formats, particularly if such rewriting will reduce the performance of the program and increase the costs of deployment.

Indeed, the need for data format standardization for interchange with other software may not be clear at the point where a program first becomes important. Eventually, however, the need for data interchange with the program becomes apparent.

There are, of course, efforts to smoothly integrate standardized data-format handling into programming languages. However, the above phenomena are not going away any time soon and there is a critical role for DFDL since it allows after-the-fact description of evolving data formats.

1.2 What is DFDL?

DFDL is a language for describing data formats. A DFDL description enables parsing, that is, it allows data to be read from its native format and presented as a data structure called the DFDL Information Set or DFDL Infoset. This information set describes the common characteristics of parsed data that are required of all DFDL implementations and it is fully defined in Section 4. DFDL implementations MAY provide API access to the Infoset as well as conversion of the Infoset into concrete representations such as XML text, binary XML [EXI], or JSON [JSON]. DFDL also enables unparsing, that is, allows data to be taken from an instance of a DFDL information set and written out to its native format.

DFDL achieves this by leveraging W3C XML Schema Definition Language (XSD) 1.0. [XSD]

An XML schema is written for the logical model of the data. The schema is augmented with special DFDL annotations and the annotated schema is called a DFDL Schema. The annotations are used to describe the native representation of the data.

This approach of extending XSD with format annotations has been extensively used in commercial systems that predate DFDL. The contribution of DFDL for data parsing is creation of a standard for these annotations that is open, comprehensive, and vendor neutral. For unparsing DFDL does more to advance the state of the art by providing some capabilities to automatically

---

3 DFDL uses the term ‘unparsing’ for symmetry with parsing. This is roughly equivalent to the terms ‘marshalling’ or ‘serialization’, but those terms both connote a sequencing order that DFDL does not impose for all formats, so DFDL uses its own distinct term.
compute fields that depend on the length or presence of other data. Prior-generation data format technologies left this difficult task up to application logic to compute.

1.2.1 Simple Example

Consider the following XML data:

```xml
<w>5</w>
<x>7839372</x>
<y>8.6E-200</y>
<z>-7.1E8</z>
```

The logical model for this data can be described by the following fragment of an XML schema document that simply provides a description of the name and type of each element:

```xml
<xs:complexType name="example1">
  <xs:sequence>
    <xs:element name="w" type="xs:int" />
    <xs:element name="x" type="xs:int" />
    <xs:element name="y" type="xs:double" />
    <xs:element name="z" type="xs:float" />
  </xs:sequence>
</xs:complexType>
```

Now, suppose the same data is represented in a non-XML format. A binary representation of the data can be visualized like this (shown as hexadecimal):

```
0000 0005 0077 9e8c
169a 54dd 0a1b 4a3f
ce29 46f6
```

To describe the same information in DFDL, the original XML schema document that described the data model is annotated (on the type definition) as follows:

```xml
<xs:complexType name="example1">
  <xs:sequence>
    <xs:element name="w" type="xs:int">
      <xs:annotation>
        <xs:appinfo source="http://www.ogf.org/dfdl/">
          <dfdl:element representation="binary"
                          binaryNumberRep="binary"
                          byteOrder="bigEndian"
                          lengthKind="implicit"/>
        </xs:appinfo>
      </xs:annotation>
    </xs:element>
    <xs:element name="x" type="xs:int">
      <xs:annotation>
        <xs:appinfo source="http://www.ogf.org/dfdl/">
          <dfdl:element representation="binary"
                          binaryNumberRep="binary"
                          byteOrder="bigEndian"
                          lengthKind="implicit"/>
        </xs:appinfo>
      </xs:annotation>
    </xs:element>
    <xs:element name="y" type="xs:double">
      <xs:annotation>
        <xs:appinfo source="http://www.ogf.org/dfdl/">
          <dfdl:element representation="binary"
                          binaryFloatRep="ieee"
                          byteOrder="bigEndian"
                          lengthKind="implicit"/>
        </xs:appinfo>
      </xs:annotation>
    </xs:element>
  </xs:sequence>
</xs:complexType>
```
This simple DFDL annotation expresses that the data are represented in a binary format and that the byte order is big endian. This is all that a DFDL parser needs to read the data.

In the above, there is a standard XML schema annotation structure:

```xml
<xs:complexType>
  <xs:sequence>
    <xs:annotation>
      <xs:appinfo source="http://www.ogf.org/dfdl/">
        <dfdl:sequence encoding="UTF-8" separator="," />
      </xs:appinfo>
    </xs:annotation>
  </xs:sequence>
</xs:complexType>
```

This encapsulates DFDL annotation elements. The source attribute on the xs:appinfo element indicates that the annotation is specifically a DFDL annotation.

Inside the xs:appinfo there is a single DFDL format annotation:

```xml
<dfdl:element representation="binary"
byteOrder="bigEndian"
lengthKind="implicit"
binaryFloatRep="ieee" />
```

Within the above annotation element, each attribute is a DFDL property, and each property-value pair is called a property binding. In the above the attribute 'representation' is a DFDL property name. Here the dfdl:element is a DFDL format annotation and the properties in it are generally called DFDL representation properties.

Consider if the same data are represented in a text format:

5,7839372,8.6E-200,-7.1E8

Once again, the same data model can be annotated, this time with properties that provide the character encoding, the field separator (comma) and the decimal separator (period):
Many properties are repeatedly expressed in the example for the sake of simplicity. Later sections of this specification define the mechanisms DFDL provides to avoid this repetition.

### 1.3 What DFDL is not

DFDL maps data from a native textual or binary representation to an instance of an information set. This can be thought of as a data transformation. However, DFDL is not intended to be a general transformation language and DFDL does not intend to provide a mechanism to map data to arbitrary XML models. There are specific limitations on the data models that DFDL can work to:

1. **DFDL uses a subset of XML Schema; in particular, XML attributes cannot be used in the data model.**
2. **The order of the data in the data model must correspond to the order and structure of the data being described.**
3. **Recursive definitions are not supported.**

Point (2) deserves some elaboration. The XML schema used must be suitable for describing the physical data format. There must be a correspondence between the XML schema’s constructs and the physical data structures. For example, generally the elements in the XML schema must match the order of the physical data. DFDL does allow for certain physically unordered formats as well.

The key concept here is that when using DFDL, one does not get to design an XML schema to one’s preference and then populate it from data. That would involve two steps: first describing the data format and second describing a transformation for mapping it to the structure of the XML schema. DFDL is only about the format part of this problem. There are other languages, such as
XSLT [XSLT], which are for transformation. In DFDL, one describes only the format of the data, and the format constrains the nature of the XML schema one must use in its description. DFDL is also not intended for describing generic formats like XML or JSON (for which schema-aware parsers exist), nor for prescriptive formats like Google Protocol Buffers [GPB] where the format is never exposed and access is via software libraries.

1.4 Scope of version 1.0
The goals of version 1.0 are as follows:
1. Leverage XML technology and concepts
2. Support very efficient parsers/formatters
3. Avoid features that require unnecessary data copying
4. Support round-tripping, that is, read and write data in a described format from the same description
5. Keep simple cases simple
6. Simple descriptions should be "human readable" to the same degree that XSD is.

The general features of version 1.0 are as follows:

a) Text and binary data parsing and unparsing
b) Validate the data when parsing and unparsing using XSD validation.
c) Defaulted input and output for missing representations
d) Reference – use of the value of a previously read element in subsequent expressions
e) Choice – capability to select among format variations
f) Hidden groups of elements – A description of an intermediate representation the corresponding Infoset items of which are not exposed in the final Infoset.
g) Basic arithmetic in DFDL expressions.
h) Out-of-type value handling (e.g., The string value 'NIL' to indicate nil for an integer)
i) Speculative parsing to resolve uncertainty.
j) Very general parsing capability: Lookahead/Push-back

Version 1.0 of DFDL is a language capable of expressing a wide range of binary and text-based data formats.

DFDL can describe binary data as found in the data structures of COBOL, C, PL1, Fortran, etc., as well as standard binary data in formats like ISO8583 [ISO8583]. DFDL can describe repeating sub-arrays where the length of an array is stored in another location of the structure.

DFDL can describe a wide variety of textual data formats such as HL7, X12, CSV, and SWIFT MT [DFDLSchemas]. Textual data formats often use syntax delimiters, such as initiators, separators and terminators to delimit fields.

DFDL has certain composition properties. i.e., two formats can be nested or concatenated and the combination results in a working format.

The following topics have been deferred to future versions of the standard:

- Extensibility: There are real examples of proprietary data format description languages that were used as the base of experience from which standard DFDL was derived. However, there are no examples of extensible format description languages. Therefore, while extensibility is desirable in DFDL, there is not yet a base of experience with extensibility from which to derive a standard.
- Rich Layering: Some formats require data to be described in multiple passes. Combining these into one DFDL schema requires very rich layering functionality. In these layers one element's value becomes the representation of another element. DFDL V1.0 allows description of only a limited kind of layering.
2 Overview of the Specification

The sections of the specification are

- Section 3, Notational and Definitional Conventions - provides definitions used throughout the specification. Note that terminology is defined at point of first use, but there is a complete Glossary in Appendix E: Glossary of Terms.
- Section 4, The DFDL Information Set (Infoset) - describes the abstract data structure produced by parsing data using a DFDL processor, and which is consumed by a DFDL processor when unparsing data. DFDL contains an expression language, and it is this data structure that the expression language operates on.
- Section 5, DFDL Schema Component Model describes the components that makes up a DFDL schema, and the subset of XML Schema that is used to express them.
- Sections 6, DFDL Syntax Basics and 7, Syntax of DFDL Annotation Elements - describes the syntactic structure of DFDL annotations and introduces the purposes of the various annotations.
- Section 8, Property Scoping and DFDL Schema Checking describes the way DFDL annotations that provide format properties are combined across the parts of the DFDL schema, and also describes static checking that is done on the DFDL schema.
- Section 9, DFDL Processing Introduction covers processing, including the core algorithms for parsing and unparsing data, as well as validation. It introduces the DFDL Data Syntax Grammar, which captures the structure of data that can be described with DFDL, and which is referenced throughout the rest of the specification.
- Section 10, Overview: Representation Properties and their Format Semantics provides an overview of, and Sections 11 to 17 describe in detail, all the DFDL properties. The properties are organized as follows:
  - Common to both Content and Framing (see Section 11)
  - Common Framing, Position, and Length (see Section 12)
  - Simple Type Content (see Section 13) - This is the largest section as it covers properties for all the various simple types, starting with properties that apply to all simple types, then properties for all types with textual representation, and then proceeding through the types, covering textual and binary format properties for each type.
    - Sequence Groups (see Section 14)
    - Choice Groups (see Section 15)
    - Array (i.e., recurring) elements and optional elements (see Section 16)
    - Calculated Values (see Section 17)
- Section 18, DFDL Expression Language covers the XPath-derived expression language that is embedded in DFDL and is used for computing the values of many properties dynamically, as well as for calculated value elements, and assertion checking.
- Section 19, DFDL Regular Expressions, covers the regular expression language used when parsing to isolate elements within the data stream, as well as to check assertions.

The remaining sections and appendices supply additional details of particular importance to implementors of DFDL, or they provide detail and reference material and are referenced from other parts of the specification.
3 Notational and Definitional Conventions

Examples of DFDL schemas provided herein are for illustration purposes only and for clarity they often do not include all the necessary DFDL properties that would be needed for a complete functional DFDL schema.

3.1 Glossary and Terminology

This specification provides definitions of the terms it uses at the point of first use. However, as this specification will not generally be read linearly, but out of order, a complete glossary is provided in Appendix E: Glossary of Terms.

The capitalized key words MUST, MUST NOT, SHALL, SHALL NOT, SHOULD, SHOULD NOT, MAY, REQUIRED, OPTIONAL, and RECOMMENDED in this document are to be interpreted as described in [RFC2119]. Such usage in capital letters is generally about DFDL implementations and their common or distinguishing characteristics.

When describing requirements for correct usage of the DFDL language by a DFDL Schema author, these same words are used, but are not capitalized. For example, the specification may state “The DFDL fillByte property must be a single byte or single character.” What is intended by “must” here is that if the value for that property does not conform, that it is a Schema Definition Error by the schema author.

Similarly, when describing characteristics of data being parsed or being unparsed, and whether that data conforms to the format described by a DFDL schema, these same words may be used. For example, the specification may state “The representation must be followed by a terminating delimiter.”, but what is intended by “must” in this case is that the consequence of the data not having that terminating delimiter is a Processing Error because the data does not comply with its format specification.

When describing data, the uncapitalized terms required and optional in this document have specific formal meanings (introduced in Section 5.3.1, MinOccurs, MaxOccurs) having to do with the way element declarations are annotated in the DFDL language. The data corresponding to such an element declaration is also said to be either required or optional, and the DFDL element declaration is said to be for a required element, or an optional element.

3.2 Failure Types

Where the phrase “MUST be consistent with” is used, it is assumed that a conforming DFDL implementation MUST check for the consistency and issue appropriate diagnostic messages when an inconsistency is found.

There are several kinds of failures that can occur when a DFDL processor is handling data and/or a DFDL schema. These are:

- **Schema Definition Error** or SDE for short - these indicate the DFDL schema is not meaningful. They are generally fatal errors that prevent or stop processing of data.

- **Processing Error** - These are errors that occur when parsing or unparsing.
  - At parse time, Processing Errors can cause the parser to search (such as via backtracking) for alternative ways to parse the data as are allowed by the DFDL schema. In that sense parse-time Processing Errors guide the parsing, and when the parser finds an alternative way to parse the data, a prior parse error is said to have been suppressed. A parse error that is not suppressed MUST terminate parsing with a diagnostic message.
  - At unparsing-time, Processing Errors are generally fatal. They MUST cause unparsing to stop with a diagnostic message.

- **Validation Error** - These are errors when optional validation checking is available and enabled. Validation Errors MUST not stop, nor influence, parsing or unparsing behavior. Validation Errors are effectively warnings indicating lack of conformance of the parser output, or the unparsers input, with the XML Schema facet constraints, or the XSD maxOccurs and XSD minOccurs values.
• **Recoverable Error** - In addition to using XML Schema validation, DFDL also provides the ability to add Recoverable Error assertions to a DFDL schema. These cause diagnostic messages to be created but MUST not stop, nor influence, parsing or unparsing behavior.
4 The DFDL Information Set (Infoset)

This section defines an abstract data set called the DFDL Information Set (Infoset). Its purpose is to define what is provided:

- to an invoking application by a DFDL parser when parsing DFDL-described data using a DFDL Schema;
- to a DFDL unparser by an invoking application when generating DFDL-described data using a DFDL Schema

The DFDL Infoset contains enough information so that a DFDL schema can be defined that enables unparsing the Infoset and reparsing the resultant data stream to produce the same Infoset.

There is no requirement for DFDL-described data to be valid in order to have a DFDL information set.

![DFDL Infoset Object Model](Figure 1)

Figure 1 DFDL Infoset Object Model

The DFDL information set is presented above in Figure 1 DFDL Infoset Object Model as an object model using a Unified Modeling Language (UML) class diagram [UML].

The structure of the information set follows the Composite design pattern [Composite]. In case of inconsistency or ambiguity, the following discussion takes precedence.

DFDL describes the format of the physical representation for data whose structure conforms to this model. Note that this model allows hierarchically nested data but does not allow representation of arbitrary connected graphs of data objects.

DFDL information sets may be created by methods (not described in this specification) other than parsing DFDL-described data.

A DFDL information set consists of a number of information items; or just items for short. The information set for any well-formed DFDL-described data contains at least a document information item and one element information item. An information item is an abstract description of a part of some DFDL-described data: each information item has a set of associated named members. In this specification, the member names are shown in square brackets, [thus]. The types of information item are listed in Section 4.2 Information Items.

The DFDL Information Set does not require or favor a specific implementation interface paradigm. This specification presents the information set as a modified tree for the sake of clarity and
simplicity, but there is no requirement that the DFDL Information Set be made available through a tree structure; other types of interfaces, including (but not limited to) event-based and query-based interfaces, are also capable of providing information conforming to the DFDL Information Set.

The terms "information set" and "information item" are similar in meaning to the generic terms "tree" and "node", as they are used in computing. However, the former terms are used in this specification to reduce possible confusion with other specific data models.

The DFDL Information Set is similar in purpose to the XML Information Set [XMLInfoset], however, it is not identical, nor a perfect subset, as there are important differences such as that the DFDL Infoset does not have ‘text’ nodes that are a primary feature of the XML Infoset, as well as that the contents of strings is much less restricted in the DFDL Infoset.

The DFDL Information Set does not have any specific support for comments. When a data format allows for textual data mixed with a comment syntax, then both that data and the content of the comments correspond to DFDL Information Items.

4.1 "No Value"

In the discussion of Information Items and their members below, some members may sometimes have the value no value, and it is said that such a member has no value. This value is distinct from all other values. In particular it is distinct from the empty string, the empty set, and the empty list, each of which simply has no members. The concept of no-value is also orthogonal to how nillable elements are represented in the Infoset, which uses a separate [nilled] boolean flag, not a distinguished value.

4.2 Information Items

An information set contains two different types of information items, as explained in the following sections. Every information item has members. For ease of reference, each member is given a name, indicated [thus].

4.2.1 Document Information Item

There is exactly one document information item in the information set, and all other information items are accessible through the [root] member of the document information item.

There is no specific DFDL schema component that corresponds to this item. It is a concrete artifact describing the information set.

The document information item has the following members:

- [root] The element information item corresponding to the root element declaration of the DFDL Schema.
- [dfdlVersion] String. The version of the DFDL specification to which this information set conforms. For DFDL V1.0 this is 'dfdl-1.0'
- [schema] String. This member is reserved for future use.

4.2.2 Element Information Items

There is an element information item for each value parsed from the non-hidden DFDL-described data. This corresponds to an occurrence of a non-hidden element declaration of simple type in the DFDL Schema and is known as a simple element information item.

There is an element information item for each explicitly declared structure in the DFDL-described data. This corresponds to an occurrence of an element declaration of complex type in the DFDL Schema and is known as a complex element information item.

In this information set, as in an XML document, an array is just a set of adjacent elements with the same name and namespace.

The [root] member of the document information item corresponds to the root element declaration of a DFDL Schema, and all other element information items are accessible by recursively following its [children] member.

An element information item has the following members:
• **[array]** Boolean. True if the item is an array, meaning that it corresponds to an element having maxOccurs value greater than 1, or ‘unbounded’.

• **[children]** An ordered set of zero or more element information items. The order they appear in the set is the order implied by the DFDL Schema. ‘Ordered set’ is not formally defined here, but two operations are assumed: ‘count’ gives the number of information items, and ‘at (index)’ gives the element at ordinal position ‘index’ starting from 1. In a simple element information item this member has no value. In a document information item this member contains exactly one element information item. If the **[nilled]** member is true, then this member has no value.

• **[dataType]** String. The name of the XML Schema 1.0 built-in simple type to which the value corresponds. DFDL supports a subset of these types listed in Section 5.1 DFDL Simple Types.

• **[dataValue]** member has no value, and for a complex element the **[children]** member has no value. If this member is true, then the Infoset item is said to be nil or nilled.

• **[document]** The document information item representing the DFDL information set that contains this element. This element is empty except in the root element of an information set.

• **[name]** String. The local part of the element name.

• **[namespace]** String. The namespace, if any, of the element. If the element does not belong to a namespace, the value is the empty string.

• **[nilled]** Boolean. True if the nullable item is nil. False if the nullable item is not nil. If the element is not nullable this member has no value. If this member is true then for a simple element the

• **[parent]** The complex element information item which contains this information item in its **[children]** member. In the root element of an information set this member is empty.

• **[schema]** String. A reference to a schema component associated with this information item, if any. If not empty, the value MUST be an absolute or relative Schema Component Designator [SCD].

• **[unionMemberSchema]** String. For simple element information items, this member contains an SCD reference to the member of the union that matched the value of the element. Empty if validation is not enabled. Empty if the element's type is not a union.

• **[valid]** Boolean. True if the element is valid as determined by a DFDL implementation that performs validation checking. A complex element information item is not valid if any of its **[children]** are not valid. Empty if validation is not enabled.

On unparsing, any non-empty values for the **[valid]** or **[unionMemberSchema]** members are ignored. However, in the augmented Infoset which is built during the unparsing operation **[valid]** will have a value, and **[unionMemberSchema]** may have a value.

### 4.3 DFDL Information Item Order

On parsing and unparsing information items are presented in the order they are defined in the DFDL Schema.

### 4.4 DFDL Augmented Infoset

When unparsing, one begins with the DFDL schema and conceptually with the logical Infoset. This Infoset can be sparsely populated because the DFDL Schema can describe default values and computations to be done to obtain the values of some elements. As unparsing progresses and fills in these defaultable and calculated elements, these new item values augment the Infoset, that is, make it bigger. The resulting Infoset is called the **augmented Infoset**. The details of this augmentation process are described in Section 9.7 Unparser Infoset Augmentation Algorithm.

---

4 Also, to support PSVI [PSVI] construction.

5 The purpose of this member is to support construction of a W3C standard Post Schema Validation Infoset (PSVI) [PSVI] from a DFDL Infoset.
5 DFDL Schema Component Model

When using DFDL, the format of data is described by means of a DFDL Schema. The DFDL Schema Component Model is shown in conceptual UML in Figure 2. The shaded boxes have direct corresponding XML Schema syntax and therefore appear in DFDL schema. The unshaded boxes are conceptual classes often used in discussion of DFDL schemas. For example, the ModelGroup class is a generalization of Sequence and Choice classes which are the concrete classes corresponding to xs:sequence and xs:choice constructs of the schema. The class Term is a further generalization encompassing not only ModelGroup, but GroupReference, ElementReference, and ElementDeclaration.

![Figure 2 DFDL Schema UML diagram](image)

Each object defined by a class in the above UML is called a DFDL Schema component. The DFDL Schema Model is expressed using a subset of the XML Schema Description Language (XSD). XSD provides a standardized schema language suitable for expressing the DFDL Schema Model.

A DFDL Schema is an XML schema containing only a restricted subset of the constructs available in full W3C XML Schema Description Language. Within this XML schema, special DFDL annotations are distributed that carry the information about the data's format or representation. A DFDL Schema is a valid XML schema. However, the converse is not true in general since the DFDL Schema Model does not include many concepts that appear in XML schema.

5.1 DFDL Simple Types

The DFDL simple types are shown in Figure 3. The graph shows all the types defined by XML Schema version 1.0, and the subset of these types supported by DFDL are shown as shaded.
Figure 3 DFDL simple types as a subset of XML Schema types

These types are defined as they are in XML Schema, with the exceptions of:

- String – In DFDL a string can contain any character codes. None are reserved (including the character with character code U+0000, which is not permitted in XML documents.)

The simple types are placed into logical type groupings as shown in this table:

<table>
<thead>
<tr>
<th>Logical Type Group</th>
<th>Types</th>
</tr>
</thead>
<tbody>
<tr>
<td>String</td>
<td>xs:string</td>
</tr>
<tr>
<td>Calendar</td>
<td>xs:dateTime, xs:date, xs:time</td>
</tr>
<tr>
<td>Opaque</td>
<td>xs:hexBinary</td>
</tr>
<tr>
<td>Boolean</td>
<td>xs:boolean</td>
</tr>
</tbody>
</table>

Table 1: Logical type groupings

Note that DFDL does not have specific types corresponding to time intervals, nor are there special numeric types for geo-coordinates, currency, or complex numbers. These concepts must be described in DFDL using the available types.

5.2 DFDL Subset of XML Schema

The DFDL subset of XSD is a general model for hierarchically nested data. It avoids the XSD features used to describe the peculiarities of XML as a syntactic textual representation of data and avoids features that are simply not needed by DFDL.

The following lists detail the similarities and differences between general XSD and this subset.

DFDL Schemas consist of:

- Standard XSD namespace management
- Standard XSD import and management for multiple file schemas
- Local element declarations with dimensionality via XSD maxOccurs and XSD minOccurs.
• Global element declarations
• Complex type definitions with empty or element-only content models.
• DFDL appinfo annotations describing the data format
• These simple types: string, float, double, decimal, integer, long, int, short, byte, nonNegativeInteger, unsignedLong, unsignedInt, unsignedShort, unsignedByte, boolean, date, time, dateTime, hexBinary
• These facets: minLength, maxLength, minInclusive, maxInclusive, minExclusive, maxExclusive, totalDigits, fractionDigits, enumeration, pattern (for xs:string type only)
• Fixed values
• Default values
• 'sequence' model groups (without XSD minOccurs and XSD maxOccurs or with both XSD minOccurs="1" and XSD maxOccurs="1")
• 'choice' model groups (without XSD minOccurs and XSD maxOccurs or with both XSD minOccurs="1" and XSD maxOccurs="1")
• Simple type derivations derived by restriction from the allowed built-in types
• Reusable Groups: named model group definitions can only contain one model group
• Element references with dimensionality via XSD maxOccurs and XSD minOccurs.
• Group references without dimensionality
• Nullable attribute is "true" (that is, nullable="true" in the element declaration.)
• Appinfo annotations for sources other than DFDL are permitted and ignored
• Unions; the memberTypes must be derived from the same simple type. DFDL annotations are not permitted on union members.6

• XML Entities
• The xs:schema "elementFormDefault" attribute
• The xs:element "form" attribute

Note: xs:nonNegativeInteger is treated as an unsigned xs:integer.

The following constructs from XML Schema are not used as part of the DFDL Schema Model of DFDL v1.0 schemas; however, they are all reserved7 for future use since the data model may be extended to use them in future versions of DFDL:
• Attribute declarations (local or global)
• Attribute references
• Attribute group definitions
• Complex type derivations where the base type is not xs:anyType.
• Complex types having mixed content models or simple content models
• List simple types
• Union simple types where the member types are not derived from the same simple type.
• These atomic simple types: normalizedString, token, Name, NCName, QName, language, positiveInteger, nonPositiveInteger, negativeInteger, gYear, gYearMonth, gMonth, gMonthDay, gDay, ID, IDREF, IDREFS, ENTITIES, ENTITY, NMToken, NMTokenS, NOTATION, anyURI, base64Binary
• XSD maxOccurs and XSD minOccurs on model groups (except if both are '1')
• XSD minOccurs = '0' on branches of xs:choice model groups
• Identity Constraints
• Substitution Groups
• xs:all groups
• xs:any element wildcards

---

6 The purpose of unions is to allow multiple constraints via facets such as multiple independent range restrictions on numbers. This enhances the ability to do rich validation of data.
7 By reserved it is intended that conforming DFDL v1.0 implementations MUST NOT assign semantics to them.
• Redefine - This version of DFDL does not support xs:redfine. DFDL schemas must not contain xs:redfine directly or indirectly in schemas they import or include.
• whitespace facet
• Recursively defined types and elements (defined by way of type, group, or element references)

5.3 XSD Facets, min/maxOccurs, default, and fixed

XSD element declarations and references can carry several properties that express constraints on the described data. These constraints are mainly used for validation. These properties include:

• the facets
• minOccurs, maxOccurs
• default
• fixed

The facets and the types they are applicable to are:

• minLength maxLength (for types xs:string, and xs:hexBinary)
• pattern
• enumeration (all types except xs:boolean)
• maxInclusive, maxExclusive, minExclusive, minInclusive (for Number and Calendar types in Section 5.1)
• totalDigits (for type xs:decimal and all supported integer types descending from xs:decimal in Section 5.1)
• fractionDigits (for type xs:decimal)

The facets (but not XSD maxOccurs nor XSD minOccurs) are also checked by the dfdl:checkConstraints DFDL expression language function.

The following sections describe these in more detail.

5.3.1 MinOccurs, MaxOccurs

XSD minOccurs and XSD maxOccurs are used in these definitions:

• An element declaration or reference where XSD minOccurs is greater than zero is said to be a required element.
• An element declaration or reference where XSD minOccurs is equal to zero is said to be an optional element.
• A required element or optional element where XSD maxOccurs is greater than 1 is also said to be an array element.

When validating, XSD minOccurs and XSD maxOccurs are used to determine the minimum and maximum valid number of occurrences of an element.

The XSD minOccurs and XSD maxOccurs values are interpreted in conjunction with the DFDL dfdl:occursCountKind property. See Section 16, Properties for Array Elements and Optional Elements, for more details.

5.3.2 MinLength, MaxLength

These facets are used:

• When dfdl:lengthKind is "implicit" and type is xs:string or xs:hexBinary. In that case the length is given by the value of the XSD maxLength facet. In this case the XSD minLength facet is required to be equal to the XSD maxLength facet (Schema Definition Error otherwise).
• For validation of variable length string elements.

5.3.3 MaxInclusive, MaxExclusive, MinExclusive, MinInclusive, TotalDigits, FractionDigits

• Used for validation only

The format of numbers is not derived from these facets. Rather DFDL properties are used to specify the format.
5.3.4 Pattern
- Allowed only on elements of type xs:string or types derived from it in Section 5.1.
- Used for validation only

It is important to avoid confusion of the pattern facet with other uses of regular expressions that are needed in DFDL (for example, to determine the length of an element by regular expression matching).

Note: in XSD, pattern is about the lexical representation of the data, and since all is text there, everything has a lexical representation. In DFDL only strings are guaranteed to have a lexical and logical value that is identical.

5.3.5 Enumeration Values
Enumerations are used to provide a list of valid values in XSD.
- Used for validation only

Note: in DFDL XSD enumerations are not used as a means to define symbolic constants. These may be captured using dfdl:defineVariable constructs so they can be referenced from expressions.

5.3.6 Default
The XSD default property is used both when parsing and unparsing, to provide the default value of an element when the situation warrants it. See 9.4 Element Defaults.

Note that the XSD fixed and XSD default properties are mutually exclusive on an element declaration.

5.3.7 Fixed
The XSD fixed property is used in the same ways as the XSD default property but in addition:
- To constrain the logical value of an element when validating.

Note that the XSD fixed and XSD default properties are mutually exclusive on an element declaration.

5.4 Compatibility with Other Annotation Language Schemas
A DFDL Schema only applies DFDL annotations on a subset of the XML Schema constructs.

Hence, one normally thinks that a DFDL schema cannot contain any of the constructs outside of the DFDL subset. For example, the DFDL subset of XML Schema does not use attributes, hence, a DFDL schema normally would not contain attribute declarations.

There is an exception to this, however. One reason to xs:include/xs:import another XML schema document is purely for its use in validating annotations within the schema itself. Such an XML schema is describing not data, but a schema language extension of non-DFDL xs:annotation elements to be used in the rest of the schema.

Hence, the complete set of files making up a schema by way of xs:include/xs:import may include a mixture of DFDL schemas that use only the DFDL subset of XSD, as well as other XML Schemas that describe just annotations. These annotation schemas are unrestricted by the DFDL subset of XML Schema. For example, they may include elements containing xs:attribute declarations.

A DFDL processor needs a way to tell these schema files apart so that it can enforce the DFDL subset in schema files that are describing data formats and ignore the XML schema files that are for unknown annotation languages that are to be ignored by the DFDL processor.

Hence, this rule: a DFDL implementation MUST ignore any schema file included or imported by a DFDL schema if the top level xs:schema element of that included/imported schema does not have an XML namespace binding for the DFDL namespace.
6 DFDL Syntax Basics

Using DFDL, a data format is described by placing special annotations at various positions within an XML schema. A DFDL processor requires these annotations, along with the structural information of the enclosing XML schema, to make sense of the physical data model.

6.1 Namespaces

The element and attribute names in the DFDL syntax are in a namespace defined by the URI http://www.ogf.org/dfdl/. All symbols in this namespace are reserved. DFDL implementations MUST NOT provide extensions to the DFDL standard using names in this namespace. Within this specification, the namespace prefix for DFDL is "dfdl" referring to the namespace http://www.ogf.org/dfdl/dfdl-1.0/.

Attributes on DFDL annotations that are not in the DFDL namespace or in no namespace are ignored by a DFDL processor.

A DFDL Schema document contains XML schema annotation elements that define and assign names to parts of the format specification. These names are defined using the target namespace of the schema document where they reside and are referenced using QNames in the usual manner. A DFDL schema document can include or import another schema document, and namespaces work in the usual manner for XML schema documents. The schema as a whole includes all additional schema documents referenced through import and include. Generally, in this specification, when referring to the DFDL Schema this is intended to mean the schema as a whole. When referring to a specific document, the term DFDL Schema document is used.

6.2 The DFDL Annotation Elements

DFDL annotations must be positioned specifically where DFDL annotations are allowed within an XML schema document. These positions are known as as annotation points. When an annotation is positioned at an annotation point, it binds some additional information to the schema component that encloses it. The description of a data format is achieved by correctly placing annotations on the structural components of the schema.

DFDL specifies a collection of annotations for different purposes. They are organized into three different annotation types: Format Annotations, Statement Annotations, and Defining Annotations.

At any single annotation point of the schema there can be only one format annotation, but there can be several statement annotations. There are rules about which of these are allowed to co-exist which are described in sections about those specific annotation types.

The resolved set of annotations for an annotation point is a combined set of annotations taken from:

1. a simple type definition and the base simple type it references.
2. an element declaration and the type definition from (1) it references.
3. an element reference and the global element declaration from (2) it references.
4. a group reference and the global group definition it references.

</tr>
</tbody>
</table>

**Table 2 - DFDL Annotation Elements**

DFDL defining annotation elements may only appear at top-level, that is, as annotation children of the xs:schema element. The order of their appearance does not matter, nor does their position relative to other children of the xs:schema.
6.3 DFDL Properties

A DFDL property is a specific DFDL construct that tells the DFDL processor some characteristic about the data format.

Properties carried on the component format annotations (See Section 7.1) are called format properties. A format property that is used to describe a physical characteristic of a component is called a representation property.

Properties on DFDL annotations may have values of one or more of the following types:

- **Enumeration**
  The property value is an XSD xs:token the value of which is one of the allowed values listed in the property description.
  
  Example: the dfdl:lengthKind property, which has values taken from "delimited", "fixed", "explicit", "implicit", "prefixed", "pattern", and "endOfParent". For example:
  
  ```
  lengthKind='delimited'
  ```

- **DFDL string literal** (Section 6.3.1):
  The property value represents a sequence of literal bytes or characters which represent data which appears in the data stream. The value type is a restriction of the XSD xs:token that further disallows the space character. DFDL entitie must be used to express whitespace in a DFDL String Literal.
  
  Example: the dfdl:terminator property, which expresses characters or bytes to be found in the data stream to mark the termination of an element or model group instance. An example terminator might be:
  
  ```
  terminator='%NL;'
  ```
  
  This uses DFL’s string-literal character class entity syntax (see Section 6.3.1.3) to express that the element or model group is terminated by a line ending in the data stream.

- **DFDL expression** (Section 6.3.2)
  The property is an xs:string the value of which is a DFDL expression that returns a value derived from other property values and/or from the DFDL Infoset. Leading and trailing whitespace is trimmed for DFDL expressions.
  
  Example: the dfdl:occursCount property takes an expression which commonly looks in the Infoset via an expression, to obtain the count from another element. An example dfdl:occursCount property might be:
  
  ```
  occursCount='{ ../hdr/count }'
  ```

- **DFDL regular expression** (Section 6.3.3)
  The property is an xs:string the value of which is a regular expression that can be used as a pattern to calculate the length of an element by applying that pattern to the sequence of literal bytes or characters which appear in the data stream. Note that leading and trailing whitespace is not trimmed and is part of the regular expression value.
  
  Example: the dfdl:lengthPattern property takes a regular expression which is used to scan the data stream for matching data. An example might be:
  
  ```
  lengthPattern="\w{1,5}\:"
  ```
  
  This scans the data stream for from 1 to 5 word-characters followed by a semi-colon character.

- **Logical Value.**
  The property value is a string that describes a logical value. The type of the logical value is one of the XML schema simple types. The string must conform to the XML schema lexical representation for the type.
  
  Example: the dfdl:nilValue property can be used to provide a logical value that if it matches the element’s logical value is used to indicate the data is nilled. For example for an element of type xs:int:

  ```
  dfdl-nilValue='false'
  ```
QName
The property value is an XML Qualified Name as specified in "Namespaces in XML" [XMLNamespaces]
Example: The dfdl:escapeSchemeRef property refers to a named escape scheme definition via its qualified name. For example:

```
escapeSchemeRef='ex:backslashScheme'
```

Some properties accept a list or union of types

- List of DFDL String Literals or Logical Values
  The property value is a whitespace separated list of the specified type. When parsing, if more than one string literal in the list matches the portion of the data stream being evaluated then the longest matching value in the list must be used. When unparsing, the first value in the list must be used. String literals containing whitespace or string literals representing the empty string must use character class entities in their syntax.
  Example: The dfdl:separator property below indicates that the items of a sequence are separated either by a comma or a tab character.

```
separator=', %HT,'
```

- Union of types and expressions.
  The property value is a union of DFDL expression and exactly one of the other types. The expression must resolve to a value of the other type.
  Example: Below are two examples of the dfdl:length property. One uses an expression that resolves to an unsigned integer, the other a literal unsigned integer.

```
length='{' xs:unsignedInt((../hdr/len))'M
length='14'
```

- Union of types.
  The property value is a union of two or more types. The type is often dependent on the value of another property.
  For example, dfdl:nilValue can be a List of DFDL String Literals or a List of Logical Values depending on dfdl:nilKind. Another example is the dfdl:alignment property which can have as its value an unsigned integer or the distinguished enum value 'implicit'.

6.3.1 DFDL String Literals
DFDL String Literals represent a sequence of literal bytes or characters which appear in the data stream. This presents the following challenges:

- the literal characters in the data stream might not be in the same character set encoding as the DFDL schema
- it may be necessary to specify a literal character which is not valid in an XML document
- it may be necessary to specify one or more raw byte values

A DFDL string literal can describe any of the following types of literal data in any combination:

- a single literal character in any encoding
- a string of literal characters in any encoding
- one or more characters from a set of related characters (e.g. end-of-line characters)
- a literal byte value

A DFDL string literal is therefore able to describe any arbitrary sequence of bytes and characters.

Details on how a string literal is matched against the data stream for parsing are given in Appendix C: Processing of DFDL String literals.
**Empty String:** The special DFDL entity %ES; is provided for describing an empty string or an empty byte sequence. The %ES; entity is the only way to do this. A DFDL string literal with value "" (the empty string) is usually invalid. There are a few properties that explicitly allow an empty DFDL String Literal, and these properties assign a property-specific meaning to the empty string value.

**Whitespace:** When whitespace must be used as part of a property value, the DFDL string literal must use entities (such as %WSP;) to represent the whitespace. (This allows a property to represent lists of DFDL string literals by using literal spaces to separate list elements.)

### 6.3.1.1 Character strings in DFDL String Literals

A literal string in a DFDL Schema is written in the character set encoding specified by the XML directive that begins all XML documents:

```xml
<?xml version="1.0" encoding="UTF-8" ?>

In this example, the DFDL schema is written in UTF-8, so any literal strings contained in it, and particularly string literals found in its representation property bindings in the format annotations, are expressed in UTF-8.

However, these strings are being used to describe features of text data that are commonly in other character set encodings. For example, a DFDL schema may describe EBCDIC data that is comma separated. A comma in EBCDIC has a single-byte code unit of 0x6B in the data, the numeric value of which does not correspond to the Unicode character code for comma which is U+002C. However, when the schema indicates that an item is "," (comma) separated and specifies this using a string literal along with specifying the 'encoding' property to be 'ebcdic-cp-us' then this means that the data are separated by EBCDIC commas regardless of what character set encoding is used to write the DFDL Schema.

```xml
<?xml version="1.0" encoding="UTF-8"?>
<xs:schema ... >
  ...
  <dfdl:format encoding="ebcdic-cp-us" separator=";"/>
  ...
</xs:schema>
```

When a DFDL processor uses the separator expressed in this manner, the string literal ",;" is translated into the character set encoding of the data it is separating as specified by the `dfdl:encoding` representation property. Hence, in this case the processor would be searching the data for a character with codepoint 0x6B (the EBCDIC comma), not a UTF-8 or Unicode (0x2C) comma which is what exists in the DFDL schema document.

### 6.3.1.2 DFDL Character Entities, Character Class Entities, and Byte Values in String Literals

DFDL character entities specify a single Unicode character and provide a convenient way to specify code points that appear in the data stream but would be difficult to specify in XML strings. For example, DFDL character entities can express common non-printable characters or code points, such as 0x00, that are not valid in XML documents. DFDL entities are based on XML entities, which can also be used in a DFDL schema. Examples:

```xml
separator='\HT';
terminator='\WSP*;\/'
fillByte='\#x00;'
textStringPadCharacter='\#x7F;'
```

In some cases, regular XML character entities may be used instead. For example, the above "\#x7F;" could be expressed as '\&#x7F;' but this is not always the case. There is no way in XSD to express the character code 0 (i.e., the ASCII NUL code point), even as an XML character entity; hence, one must often use DFDL character entities like \%x00; above, or their named equivalents. The DFDL string literal syntax allows the author to always use DFDL character entity syntax instead of jumping back and forth between XSD character entities and DFDL character entities.
The following grammar gives the syntax of DFDL String Literals generally, including the various kinds of entities.

```
DfdlStringLiteral ::= (DfdlStringLiteralPart)+ | DfdlESEntity
DfdlStringLiteralPart ::= LiteralString | DfdlCharEntity | DfdlCharClass | ByteValue
LiteralString ::= A string of literal characters
DfdlCharEntity ::= '%' DfdlCharEntityName ';'
DfdlCharClass ::= '%%' DfdlCharClassName ';'
ByteValue ::= '%#r' [0-9a-fA-F]{2} ';'
DfdlEntity ::= '%%' [0-9]+ ';'
HexadecimalCodePoint ::= '%#x' [0-9a-fA-F]+ ';'
DfdlEntityName ::= 'NL' | 'SOH' | 'STX' | 'ETX' | 'EOT' | 'ENQ' | 'ACK' | 'BEL' | 'BS' | 'HT' | 'LF' | 'VT' | 'FF' | 'CR' | 'SO' | 'SI' | 'DLE' | 'DC1' | 'DC2' | 'DC3' | 'DC4' | 'NAK' | 'SYN' | 'ETB' | 'CAN' | 'EM' | 'SUB' | 'ESC' | 'FS' | 'GS' | 'RS' | 'US' | 'SP' | 'DEL' | 'NBSP' | 'NEL' | 'LS'
DfdlCharClassName ::= DfdlNLEntity | DfdlWSPEntity | DfdlWSPStarEntity | DfdlWSPPlusEntity
DfdlNLEntity ::= 'NL'
DfdlWSPEntity ::= 'WSP'
DfdlWSPStarEntity ::= 'WSP*'
DfdlWSPPlusEntity ::= 'WSP+'
DfdlESEntity ::= 'ES'
```

Table 3 DFDL Character Entity, Character Class Entity, and Byte Value Entity Syntax

Using %% inserts a single literal "%" into the string literal. This "%" is subject to character set encoding translation as is any other character.

A HexadecimalCodePoint provides a hexadecimal representation of the character's code point in ISO/IEC 10646.

A DecimalCodePoint provides a decimal representation of the character's code point in ISO/IEC 10646.

A DfdlEntityName is one of the mnemonics given in the following tables.

<table>

<td>Used in whitespace separated lists when empty string is one of the values.</td>
</tr>
</tbody>
</table>

| Table 5 DFDL Character Class Entities |
6.3.1.4 **DFDL Byte Value Entities in DFDL String Literals**

DFDL byte-value entities provide a way to specify a single byte as it appears in the data stream without any character set encoding translation. To specify a string of byte values, a sequence of two or more byte-value entities must be used. The syntax is in Table 3 DFDL Character Entity, Character Class Entity, and Byte Value Entity Syntax above. Example:

```
%#rFF;
```

In this notation the "r" can be thought of as short for "raw", as byte value entities are said to denote "raw bytes".

6.3.2 **DFDL Expressions**

Some DFDL properties allow DFDL expressions (see Section 18 DFDL Expression Language) to be used so that the property can be set dynamically at processing-time.

The general syntax of expressions is "{" expression "}".

The rules for recognizing DFDL expressions are:

- Discard any leading and trailing whitespace.
- Must start with a '{' in the first position and end with '}' in the last position.
- '{' in any position other than the first is treated as a literal.
- '}' in any position other than the last position is treated as a literal.
- '{' as the first characters are treated as the literal '{' and not as the start of a DFDL expression.

DFDL expressions reference other items in the Infoset or augmented Infoset using absolute or relative paths.

DFDL expressions that are used to provide the value of DFDL properties in the dfdl:format annotation on the top level xs:schema declaration must not contain relative paths.

6.3.3 **DFDL Regular Expressions**

Some properties expect a regular expression to be specified. The DFDL Regular Expression language is defined in Section 19, DFDL Regular Expressions.

6.3.4 **Enumerations in DFDL**

Some DFDL properties accept an enumerated list of valid values. It is a Schema Definition Error if a value other than one of the enumerated values is specified. The case of the specified value must match the enumeration. An enumeration is of type string unless otherwise stated.
7 Syntax of DFDL Annotation Elements
This section describes the syntax of each of the DFDL annotation elements along with discussion of their basic meanings.

The DFDL annotation elements are listed in Table 2 - DFDL Annotation Elements

7.1 Component Format Annotations
A data format can be 'used' or put into effect for a part of the schema by use of the component format annotation elements.

There are specific annotations for each type of schema component that supports only the representation properties applicable to that component. The table below gives the specific annotation for each schema component.

<table>
<thead>
<tr>
<th>Schema component</th>
<th>DFDL annotation</th>
</tr>
</thead>
<tbody>
<tr>
<td>xs:choice</td>
<td>dfdl:choice</td>
</tr>
<tr>
<td>xs:element</td>
<td>dfdl:element</td>
</tr>
<tr>
<td>xs:element reference</td>
<td>dfdl:element</td>
</tr>
<tr>
<td>xs:group reference</td>
<td>dfdl:group</td>
</tr>
<tr>
<td>xs:schema</td>
<td>dfdl:format</td>
</tr>
<tr>
<td>xs:sequence</td>
<td>dfdl:sequence</td>
</tr>
<tr>
<td>xs:simpleType</td>
<td>dfdl:simpleType</td>
</tr>
</tbody>
</table>

Table 6 DFDL Component Format Annotations

Below are a few examples followed by sections which describe each kind of annotation element in detail. Here is an example of DFDL component format annotation, specifically use of dfdl:element on an xs:element declaration:

```xml
<xs:schema ...>
  ...
  <xs:element name="root">
    <xs:annotation>
      <xs:appinfo source="http://www.ogf.org/dfdl/">
        <dfdl:element ref="aBaseConfig"
           representation="text"
           encoding="UTF-8"/>
      </xs:appinfo>
    </xs:annotation>
  </xs:element>
  ...
</xs:schema>
```

Note that in the above, the DFDL annotation lives inside this surrounding context of xs:annotation and xs:appinfo elements. This is just the standard XSD way of doing annotations. The source attribute is an identifier that separates different families of appinfo annotations.

Below a dfdl:format annotation is used inside a dfdl:defineFormat annotation to define a named reusable set of format properties that can be referenced from another format annotation:

```xml
<xs:schema ...>
  ...
  <xs:annotation>
    <xs:appinfo source="http://www.ogf.org/dfdl/">
      <dfdl:defineFormat name="baseFormat">
        <dfdl:format byteOrder="bigEndian" encoding="ascii"/>
      </dfdl:defineFormat>
    </xs:appinfo>
  </xs:annotation>
  ...
</xs:schema>
```
A dfdl:format annotation at the top level of a schema, that is as an annotation child element on the xs:schema, provides a set of default properties for the lexically enclosed schema document. (See 8.1.2 Providing Defaults for DFDL properties.)

7.1.1 Property Binding Syntax

A property binding is the syntax in a DFDL schema that gives a value to a property. Up to this point, the examples in this document have all used a specific syntax for property bindings called attribute form. However, the format properties may be specified in any one of three forms:

1. Attribute form
2. Element form
3. Short form

A DFDL property may be specified using any of the forms with the following exceptions:

- The dfdl:ref property may be specified in attribute or short form
- The dfdl:escapeSchemeRef property may be specified in attribute or short form
- The dfdl:hiddenGroupRef property may be specified in attribute or short form
- The dfdl:prefixLengthType property may be specified in attribute or short form
- Short form must not be used on the xs:schema element.

It is a Schema Definition Error if the same property is specified in more than one form. That is, there is no priority ordering where one form takes precedent over another.

7.1.1.1 Property Binding Syntax: Attribute Form

Within the format annotation elements are bindings for properties of the form:

| PropertyName="Value" |

For example:

```xml
<xs:annotation>
  <xs:appinfo source="http://www.ogf.org/dfdl/">
    <dfdl:format encoding="utf-8" separator="%NL;"/>
  </xs:appinfo>
</xs:annotation>
```

This is the attribute form of property binding.
7.1.1.2 Property Binding Syntax: Element Form

The representation properties can sometimes have complex syntax, so an element form for
individual property bindings is provided to ease syntactic expression difficulties. The annotation
element is dfdl:property and it has one attribute 'name' which provides the name of the property.

For example:

```
<xs:annotation>
  <xs:appinfo source="http://www.ogf.org/dfdl/">
    <dfdl:format>
      <dfdl:property name='encoding'>utf-8</dfdl:property>
      <dfdl:property name='separator'>%NL;</dfdl:property>
    </dfdl:format>
  </xs:appinfo>
</xs:annotation>
```

Element form is mostly used for properties that themselves contain the quotation mark characters
and escape characters so that the property value can be expressed without concerns about
confusion with the XSD syntax use of these same characters. XML's CDATA encapsulation can
be used to allow malformed XML and mismatched quotes to be easily used as representation
property values.

Here is an example where a delimiter has a syntax that overlaps with what XML comments look
like. Use of XML's CDATA bracketing makes this less clumsy to express than using XML escape
characters:

```
<dfdl:property name='initiator'><![CDATA[
<!--
]]></dfdl:property>
```

7.1.1.3 Property Binding Syntax: Short Form

To save textual clutter, short-form syntax for format annotations is also allowed on xs:element,
xs:sequence, xs:choice, xs:group (for group references only), and xs:simpleType schema
elements. The xs:schema element cannot carry short-form annotations; attribute form must be
used instead. Attributes which are in the namespace 'http://www.ogf.org/dfdl/dfdl-1.0/' and whose
local name matches one of the DFDL representation properties are assumed to be equivalent to
specific DFDL attribute form annotations.

For example, the two forms below are equivalent in that they describe the same data format. The
first is the short form of the second:

```
<xs:element name="elem1">
  <xs:complexType>
    <xs:sequence dfdl:separator="%HT;" />
    ...
  </xs:sequence>
</xs:complexType>
</xs:element>

<xs:element name="elem2">
  <xs:complexType>
    <xs:sequence>
      <xs:annotation><xs:appinfo source="http://www.ogf.org/dfdl/">
        <dfdl:sequence separator="%HT;" />
      </xs:appinfo></xs:annotation>
      ...
    </xs:sequence>
  </xs:complexType>
</xs:element>
```

Another example:

```
<xs:sequence dfdl:separator="","">
  <xs:element name="elem1" type="xs:int" maxOccurs="unbounded"
    dfdl:representation="text"
    dfdl:textNumberRep="standard"
    dfdl:initiator="["
```
The above show use of short-form property binding syntax for annotating elements and sequences.

### 7.1.2 Empty String as a Representation Property Value

DFDL provides no mechanism to un-set a property. Setting a representation property’s value to the empty string doesn’t remove the value for that property but sets it to the empty string value. This may not be a valid value for certain properties.

For example, in non-delimited text data formats, it is sensible for the separator to be defined to be the empty string. This turns off use of separator delimiters. For many other string-valued properties, it is a Schema Definition Error to assign them the empty string value. For example, the character set encoding property (dfdl:encoding) cannot be set to the empty string.

### 7.2 dfdl:defineFormat - Reusable Data Format Definitions

To avoid error-prone redundant expression of properties in DFDL schemas, a collection of DFDL properties can be given a name so that they are reusable by way of a *format reference*. One or more dfdl:defineFormat annotation elements can appear within the annotation children of the xs:schema element.

Each dfdl:defineFormat has a required name attribute.

The construct creates a named data format definition. The value of the name attribute is of XML type NCName. The format name becomes a member of the schema’s target namespace. These names must be unique within the namespace.

If multiple format definitions have the same 'name' attribute, in the same namespace, then it is a Schema Definition Error.

Here is an example of a format definition:

```xml
<xs:schema ...>
  <xs:annotation>
    <xs:appinfo source="http://www.ogf.org/dfdl/">
      <dfdl:defineFormat name="baseFormat">
        <dfdl:format representation="text" encoding="ascii"/>
      </dfdl:defineFormat>
    </xs:appinfo>
  </xs:annotation>
  ...
</xs:schema>
```

A dfdl:defineFormat serves only to supply a named definition for a format for reuse from other places. It does not cause any use of the representation properties it contains to describe any actual data.

### 7.2.1 Using/Referencing a Named Format Definition: The dfdl:ref Property

A named, reusable, dfdl:defineFormat definition is used by referring to its name from a format annotation using the dfdl:ref property. For example, here this annotation reuses the format named 'baseFormat':

```xml
<dfdl:element ref="baseFormat" encoding="ebcdic-cp-us"/>
```
The behavior of this dfdl:element definition is as if all representation properties defined by the named dfdl:defineFormat definition for 'baseFormat' were instead written directly on this dfdl:element annotation; however, these are superseded by any representation properties that are defined here such as the dfdl:encoding property in the example above.

7.2.2 Inheritance for dfdl:defineFormat

A dfdl:defineFormat declaration can inherit from another named format definition by use of the dfdl:ref property of the dfdl:format annotation. This allows a single-inheritance hierarchy that reuses definitions. When one definition extends another in this way, any property definitions contained in its direct elements override those in any inherited definition.

An example format that inherits from a named format definition is:

```xml
<xs:schema ...>
  <xs:annotation>
    <xs:appinfo source="http://www.ogf.org/dfdl/">
      <dfdl:defineFormat name="myConfig" >
        <dfdl:format representation="binary"
          ref="baseFormat" />
      </dfdl:defineFormat>
    </xs:appinfo>
  </xs:annotation>
  ...
</xs:schema>
```

Conceptually, the dfdl:ref inheritance chains can be flattened and removed by copying all inherited property bindings and then superseding those for which there is a local binding. Throughout this document the discussion assumes inheritance is fully flattened. That is, all dfdl:ref inheritance is first removed by flattening before any other examination of properties occurs.

It is a Schema Definition Error if use of the dfdl:ref property results in a circular path.

7.3 The dfdl:defineEscapeScheme Defining Annotation Element

One or more dfdl:defineEscapeScheme annotation elements can appear within the annotation children of the xs:schema. The dfdl:defineEscapeScheme elements may only appear as annotation children of the xs:schema.

The order of their appearance does not matter, nor does their position relative to other annotation or non-annotation children of the xs:schema.

Each dfdl:defineEscapeScheme has a required name attribute and a required dfdl:escapeScheme child element.

The construct creates a named escape scheme definition. The value of the name attribute is of XML type NCName. The name becomes a member of the schema's target namespace. These names must be unique within the namespace among escape schemes.

If multiple dfdl:defineEscapeScheme definitions have the same 'name' attribute, in the same namespace, then it is a Schema Definition Error.

Each dfdl:defineEscapeScheme annotation element contains a dfdl:escapeScheme annotation element as detailed below.

Here is an example of an escapeScheme definition:

```xml
<xs:schema ...>
  <xs:annotation>
    <xs:appinfo source="http://www.ogf.org/dfdl/">
      <dfdl:defineEscapeScheme name="myEscapeScheme">
        <dfdl:escapeScheme escapeKind="escapeCharacter"
          escapeCharacter="/" />
      </dfdl:defineEscapeScheme>
    </xs:appinfo>
  </xs:annotation>
</xs:schema>
```
A `defineEscapeScheme` serves only to supply a named definition for a `escapeScheme` for reuse from other places. It does not cause any use of the representation properties it contains to describe any actual data.

### 7.3.1 Using/Referencing a Named escapeScheme Definition

A named, reusable, escape scheme is used by referring to its name from a `escapeSchemeRef` property on an element. For example:

```xml
<xs:element name="foo" type="xs:string">
    <xs:annotation>
        <xs:appinfo source="http://www.ogf.org/dfdl/"
            escapeSchemeRef="myEscapeScheme"/>
    </xs:annotation>
</xs:element>
```

### 7.4 The dfdl:escapeScheme Annotation Element

The `escapeScheme` annotation is used within a `defineEscapeScheme` annotation to group the properties of an escape scheme and allows a common set of properties to be defined that can be reused. An escape scheme defines the properties that describe the text escaping rules in force when data such as text delimiters are present in the data. There are two variants on such schemes,

- The use of a single escape character to cause the next character to be interpreted literally. The escape character itself is escaped by the escape-escape character.
- The use of a pair of escape strings to cause the enclosed group of characters to be interpreted literally. The ending escape string is escaped by the escape-escape character.

On parsing, the escape scheme is applied after pad characters are trimmed and on unparsing before pad characters are added.

DFDL does not perform any substitutions for ampersand notations like `&lt;`.

The properties of `escapeScheme` are defined in Section 13.2.1 `The dfdl:escapeScheme Properties`.

### 7.5 The dfdl:assert Statement Annotation Element

The `assert` statement annotation element is used to assert truths about a DFDL model that are used when parsing to ensure that the data are well-formed. They are not used when unparsing.

There is a critical distinction between `assert` checks and XSD validation checks. The `assert` checks guide parsing and the creation of the DFDL Infoset by causing Processing Errors on failure. Conversely XSD validation inspects the values within the Infoset. Validation failures never affect whether the parser is able to produce a DFDL Infoset.

The `assert` checks are performed even when validation is off.

Examples of `assert` elements are below:

```xml
<dfdl:assert message="Value is not zero." test="{ ..//x eq 0}" />
<dfdl:assert message="Precondition violation." test="{ ../x le 0 and ../y ne "--" and ../y ne "<!" }"
</dfdl:assert>
<dfdl:assert message="Postcondition violation." testKind='expression'
    test="{ ../x ne "1"}"
</dfdl:assert>
```
7.5.1 Properties for dfdl:assert

A dfdl:assert annotation contains a test expression or a test pattern. The dfdl:assert is said to be successful if the test expression evaluates to true or the test pattern returns a non-zero length match, and unsuccessful if the test expression evaluates to false or the test pattern returns a zero length match. An unsuccessful dfdl:assert causes either a Processing Error or a Recoverable Error to be issued, as specified by the failureType property of the dfdl:assert.

The testKind property specifies whether an expression or pattern is used by the dfdl:assert. The expression or pattern can be expressed as an attribute or as a value.

```xml
<dfdl:assert test="{test expression}" />
<dfdl:assert>
  {test expression}
</dfdl:assert>
```

It is a Schema Definition Error if a test expression or test pattern is specified in more than one form.

It is a Schema Definition Error if both a test expression and a test pattern are specified.

A dfdl:assert can appear as an annotation on these schema components:

- an xs:element declaration (local or global)
- an xs:element reference
- an xs:group reference
- an xs:sequence
- an xs:choice
- an xs:simpleType definition (local or global)

If the resolved set of statement annotations for a schema component contains multiple dfdl:assert statements, then those with testKind 'pattern' are executed before those with testKind 'expression' (the default). However, within each group the order of execution among them is not specified.

If one of the resolved set of asserts for a schema component is unsuccessful, and the failureType of the assert is 'processingError', then no further asserts in the set are executed.

<table>

Table 7 dfdl:assert properties

Example of a dfdl:assert with a message expression:

```xml
dfdl:assert message="{ fn:concat('unknown case ', ../data1) }">
  { if (...pred1...) then ...expr1...
  else if (...pred2...) then ...expr2...
```

dfdl-wg@ogf.org
The message specified by the message property is issued only if the dfdl:assert is unsuccessful, that is, the test expression evaluates to false or the test pattern returns a zero-length match. If so, and the message property is an expression, the message expression is evaluated at that time.

If a Processing Error or Schema Definition Error occurs while evaluating the message expression, a Recoverable Error is issued to record this error (containing implementation-dependent content), then processing of the assert continues as if there were no problem and in a manner consistent with the failureType property, but using an implementation-dependent substitute message.

7.6 The dfdl:discriminator Statement Annotation Element

DFDL discriminator statement annotations are used during parsing to:

1. resolve points of uncertainty (choices, optional elements, array repetition) that cannot be resolved by speculative parsing. See Section 9.1 Parser Overview.
2. remove ambiguity during speculative parsing
3. improve diagnostic behavior when a DFDL parser encounters malformed data.

Discriminators are not used during unparsing.

A DFDL discriminator may contain a test expression that evaluates to true or false. The discriminator is said to be successful if the test evaluates to true and unsuccessful (or fails) if the test evaluates to false. A discriminator may alternatively contain a test regular expression pattern and the discriminator is successful if the test pattern matches with non-zero length and is unsuccessful (or fails) if there is no match or a zero-length match.

A discriminator determines the existence or non-existence of a schema component in the data stream. If the discriminator is successful, then the component is said to be known to exist, and any subsequent errors do not cause backtracking at the nearest point of uncertainty. Details of the behavior of a DFDL parser and the role of discriminators are given in Section 9.3 Parsing Algorithm.

Discriminators can also be used to force a resolution earlier during the parsing of a model group so that subsequent parsing errors are treated as Processing Errors of a known schema component rather than a failure to find that schema component. This may greatly improve the efficiency of DFDL parsing in some implementations, as well as improving the diagnostic information provided by a DFDL parser when given malformed data.

Examples of dfdl:discriminator annotation are below:

```
<dfdl:discriminator>
  { ../recType eq 0 }
</dfdl:discriminator>

<dfdl:discriminator test="{ ../recType eq 0 }" />
```

When the discriminator's expression evaluates to "false", then it causes a Processing Error, and the discriminator is said to fail.

7.6.1 Properties for dfdl:discriminator

Within a dfdl:discriminator, the testKind property specifies whether an expression or pattern is used by the dfdl:discriminator. The expression or pattern can be expressed as an attribute or as a value.

```
<dfdl:discriminator test="{test expression}" />
<dfdl:discriminator>
  { test expression }
</dfdl:discriminator>
```

It is a Schema Definition Error if the test expression or test pattern is specified in more than one form.
It is a Schema Definition Error if both a test expression and a test pattern are specified. A dfdl:discriminator can be an annotation on these schema components:

- an xs:element declaration (local or global)
- an xs:element reference
- an xs:group reference
- an xs:sequence
- an xs:choice
- an xs:simpleType definition (local or global)

The resolved set of statement annotations for a schema component can contain only a single dfdl:discriminator or one or more dfdl:assert annotations, but not both. To clarify: dfdl:assert annotations and dfdl:discriminator annotations are exclusive of each other. It is a Schema Definition Error otherwise.

<table>
<thead>
<tr>

<td>DFDL Regular Expression</td>
</tr>
<tr>
<td></td>
<td>Applies when testKind is 'pattern'</td>
</tr>
<tr>
<td></td>
<td>A DFDL regular expression that is applied against the data stream starting at the data position corresponding to the beginning of the representation. Consequently, the framing (including any initiator) is visible to the pattern at the start of the component on which the dfdl:discriminator is positioned.</td>
</tr>
<tr>
<td></td>
<td>If the pattern matching of the regular expression reads data that cannot be decoded into characters of the current encoding, then the behavior is controlled by the dfdl:encodingErrorPolicy property. See Section 11.2.1 Property dfdl:encodingErrorPolicy for details.</td>
</tr>
</tbody>
</table>
If the length of the match is zero then the dfdl:discriminator evaluates to false and a Processing Error is raised. If the length of the match is non-zero then the dfdl:discriminator evaluates to true.

It is a Schema Definition Error if testKind is 'pattern', and a pattern is not supplied by either the value of the dfdl:discriminator element or the value of the testPattern property.

It is a Schema Definition Error if there is no value for the dfdl:encoding property in scope.

It is a Schema Definition Error if dfdl:leadingSkip is other than 0.

It is a Schema Definition Error if the dfdl:alignment is not 1 or 'implicit'.

Annotation: dfdl:discriminator

<table>
<thead>
<tr>
<th>message</th>
<th>String or DFDL Expression</th>
</tr>
</thead>
<tbody>
<tr>

<tr>
<td>The DFDL Expression must return type xs:string. Any element referred to by the message expression must have already been processed or must be a descendent of this element. There is special treatment for errors that occur while evaluating the message expression. See below for details.</td>
<td></td>
</tr>
</tbody>
</table>

Annotation: dfdl:discriminator

### Table 8 dfdl:discriminator properties

The message specified by the message property is issued only if the discriminator is unsuccessful, that is, the test expression evaluates to false or the test pattern returns a zero-length match. If so, and the message property is an expression, the message expression is evaluated at that time.

If a Processing Error or Schema Definition Error occurs while evaluating the message expression, a Recoverable Error is issued to record this error (containing implementation-dependent content), then processing of the discriminator continues as if there were no problem, but in the case of failure using an implementation-dependent substitute message.

Examples of dfdl:discriminator annotations:

```xml
<xs:sequence>
  <xs:choice>
    <xs:element name='branchSimple' />
    <xs:annotation>
      <xs:appinfo source="http://www.ogf.org/dfdl/*">
        <dfdl:discriminator test='{. eq "a"}' />
      </xs:appinfo>
    </xs:annotation>
  </xs:element>

  <xs:element name='branchComplex' />
  <xs:annotation>
    <xs:appinfo source="http://www.ogf.org/dfdl/*">
      <dfdl:discriminator test='{./identifier eq "b"}' />
    </xs:appinfo>
  </xs:annotation>
  <xs:complexType>
    <xs:sequence>
      <xs:element name='identifier' />
    </xs:sequence>
  </xs:complexType>
</xs:element>
```
7.7 DFDL Variable Annotations

DFDL Variables provide a means for communication and parameterization within a DFDL schema. Use of variables increases the modularity of a schema by enabling some parts of a schema to be parameterized so that they are reusable.

There are 3 DFDL annotation elements associated with DFDL variables:

- `dfdl:defineVariable` - defines a variable and creates a global instance of it.
- `dfdl:newVariableInstance` - creates a scoped instance of a variable.
- `dfdl:setVariable` - assigns the value of a variable instance, which can be global or scoped.

Variables are defined at the top-level of a schema and have a specific simple type. A distinction is made between the variable as defined, and an instance of the variable where a value can be stored.

The `dfdl:defineVariable` annotation defines the name, type, and optionally default value for the variable. It is like defining a class of variables, instances of which actually store values. The `dfdl:defineVariable` also introduces a single unique global instance of the variable. Additional instances may be allocated in a stack-like fashion using `dfdl:newVariableInstance` which causes new instances to come into existence upon entry to the scope of a model group, and these instances go away on exit from the same.

DFDL variables only vary in the sense that different instances of the same variable can have different values. A single instance of a variable only ever takes on a single value. Each variable instance is a single-assignment location for a value9. Once a variable instance’s value has been read, it can never be assigned again. If it has not yet been assigned, and its default value has not been read, then a variable instance can be assigned once using `dfdl:setVariable`.

Variables are used by referencing them in DFDL expressions by prefixing their QNames with ‘$’. More information about variables and how they work operationally is in Section 18.2 Variables. The remaining sub-sections of this section focus only on the variable-related DFDL annotations and their syntax.

---

9 The rationale for single-assignment variables is to keep DFDL schemas declarative by preventing variables from being used as algorithmic accumulators. See the Appendix B: Rationale for Single-Assignment Variables.
7.7.1 dfdl:defineVariable Annotation Element

A global variable is introduced using dfdl:defineVariable:

```xml
<dfdl:defineVariable
    name = NCName
    type? = QName
    defaultValue? = logical value or dfdl expression
    external? = 'false' | 'true'>
    <!---- Contains: logical value or dfdl expression (default value) -->
</dfdl:defineVariable>
```

The name of a newly defined variable is placed into the target namespace of the schema containing the annotation. Variable names are distinct from format and escape scheme names and so cannot conflict with them. A variable can have any type from the DFDL subset of XML schema simple types. If no type is specified, the type is xs:string.

The defaultValue is optional. This is a literal value or an expression which evaluates to a constant, and it can be specified as an attribute or as the element value. If specified, the default value must match the type of the variable (otherwise it is a Schema Definition Error). If the defaultValue is given by an expression that expression must not contain any relative path (otherwise it is a Schema Definition Error).

Note that the syntax supports both a defaultValue attribute and the default value being specified by the element value. Only one or the other may be present (otherwise it is a Schema Definition Error). To set the default value to "" (empty string), the defaultValue attribute syntax must be used, or the expression { "" } must be used as the element value.

Note also that the value of the name attribute is an NCName (non-colon name - that is, may not have a prefix). The name of a variable is defined in the target namespace of the schema containing the definition. If multiple dfdl:defineVariable definitions have the same 'name' attribute in the same namespace then it is a Schema Definition Error.

A default instance of the variable is automatically created (with global scope) at the start of a DFDL parse or unpars. Additional instances of a variable can be created with the scope of other schema components. See Section 7.7.2 The dfdl:newVariableInstance Statement Annotation Element.

The external property is optional. If not specified it takes the default value 'false'. If true, the value may be provided by the DFDL processor and this external value is used as the global default value overriding any defaultValue specified on the dfdl:defineVariable annotation. The mechanism by which the processor provides this value is implementation-defined.

A variable instance gets its value either from the default value provided in the dfdl:defineVariable definition, from an external binding of the variable if the definition has the external attribute, from a dfdl:setVariable statement (See Section 7.7.3, The dfdl:setVariable Statement Annotation Element), or from the default value of a dfdl:newVariableInstance statement (See Section 7.7.2 The dfdl:newVariableInstance Statement Annotation Element.)

There is no required order between dfdl:defineVariable and other schema level defining annotations or a dfdl:format annotation that may refer to the variable.

A defaultValue expression MUST be evaluated before processing of the data stream begins.

A defaultValue expression can refer to other variables but not to the Infoset (so no path locations). When a defaultValue expression references other variables, the referenced variables each must either have a defaultValue or be external. It is a Schema Definition Error otherwise.

If a defaultValue expression references another variable then the single-assignment nature of variables prevents the referenced variable's value from ever changing, that is, it is considered to be a read of the variable's value, and once read, a variable's value cannot be changed.

If a defaultValue expression references another variable and this causes a circular reference, it is a Schema Definition Error.

It is a Schema Definition Error if the type of the variable is a user-defined simple type restriction.
7.7.1.1 Examples

```xml
<dfdl:defineVariable name="EDIFACT_DS" type="xs:string"
    defaultValue="", />
<dfdl:defineVariable name="codepage" type="xs:string"
    external="true">utf-8</dfdl:defineVariable>
```

7.7.1.2 Predefined Variables

The following variables are predefined, and their names are in the DFDL namespace (http://www.ogf.org/dfdl/dfdl-1.0/)

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Default value</th>
<th>External</th>
</tr>
</thead>
<tbody>
<tr>
<td>dfdl:encoding</td>
<td>xs:string</td>
<td>'UTF-8'</td>
<td>true</td>
</tr>
<tr>
<td>dfdl:byteOrder</td>
<td>xs:string</td>
<td>'bigEndian'</td>
<td>true</td>
</tr>
<tr>
<td>dfdl:binaryFloatRep</td>
<td>xs:string</td>
<td>'ieee'</td>
<td>true</td>
</tr>
<tr>
<td>dfdl:outputNewLine</td>
<td>xs:string</td>
<td>'%LF;'</td>
<td>true</td>
</tr>
</tbody>
</table>

Table 9 Pre-defined variables

These variables are expected to be commonly set externally so are predefined for convenience. Below the DFDL encoding property is being set to the value of a DFDL expression (between "{" and "}"), and that expression just returns the value of the dfdl:encoding variable which is being referenced as $dfdl:encoding below.

```xml
<xs:element name="title" type="xs:string">
    <xs:annotation>
        <xs:appinfo source="http://www.ogf.org/dfdl/">
            <dfdl:element encoding="{$dfdl:encoding}" />
        </xs:appinfo>
    </xs:annotation>
</xs:element>
```

7.7.2 The dfdl:newVariableInstance Statement Annotation Element

Scoped instances of defined variables are created using dfdl:newVariableInstance:

```xml
<dfdl:newVariableInstance
    ref = QName
    defaultValue? = logical value or dfdl expression >
</dfdl:newVariableInstance>
```

All instances share the same name, type, and default value if provided, but they have distinct storage for separate values using a stack-like mechanism where a new instance is introduced for a model group. These new instances are associated with a schema component using dfdl:newVariableInstance. These instances have the lifetime of the schema component. While that schema component is being parsed/unparsed, the new variable instance is used and other scoped variable instances for the same variable are not available.

Since an initial global instance is created when the variable is defined, the use of dfdl:newVariableInstance is optional.

The dfdl:newVariableInstance annotation can be used on a group reference, sequence or choice only. It is a Schema Definition Error otherwise.

The lifetime of the instance of a variable is the dynamic scope of the schema component and its content model and so is inherited by any contained constructs or construct references.

The ref property is a QName. That is, it may be qualified with a namespace prefix.

An optional defaultValue for the instance may be specified. It can be specified as an attribute or as the element value. The expression must not contain forward references to elements which
have not yet been processed nor to the current component. If specified the default value must
match the type of the variable as specified by dfdl:defineVariable. If the instance is not assigned a
new default value then it inherits the default value specified by dfdl:defineVariable or externally
provided by the DFDL processor. If a default value is not specified (and has not been specified by
dfdl:defineVariable) then the value of this instance is undefined until explicitly set (using
dfdl:setVariable).

If a default value is specified this initial value of the instance is created when the instance is
created. The value overrides any (global) default value which was specified by dfdl:defineVariable
or which was provided externally to the DFDL processor. A variable instance with a valid value
(specified or default) can be referenced anywhere within the scope of the element on which the
instance was created.

Note that the syntax supports both a defaultValue attribute and the default value being specified
by the annotation element value. Only one or the other may be present. (Schema definition error
otherwise.)

To set the default value to "" (empty string), the defaultValue attribute syntax must be used, or the
expression { "" } must be used as the element value.

The resolved set of annotations for a component may contain multiple dfdl:newVariableInstance
statements. They must all be for unique variables; it is a Schema Definition Error otherwise. The
order of execution is specified in Section 9.5 Evaluation Order for Statement Annotations.

There is no short form syntax for creating variable instances.

### 7.7.2.1  Examples

```xml
<dfdl:newVariableInstance ref="EDIFACT_DS" defaultValue="","/>
<dfdl:newVariableInstance ref="lengthUnitBits">
  { if (../../../hdr/fmtCode eq "bits") then 1 else 8 }
</dfdl:newVariableInstance>
```

### 7.7.3  The dfdl:setVariable Statement Annotation Element

Variable instances get their values either by default, by external definition, or by subsequent
assignment using the dfdl:setVariable statement annotation.

```xml
<dfdl:setVariable
  ref = QName
  value? = logical value or dfdl expression >
<!-- Contains: logical value or dfdl expression (value) -->
</dfdl:setVariable>
```

The dfdl:setVariable annotation can be used on a simple type, group reference, sequence or
choice. It may be used on an element or element reference only if the element is of simple type. It
is a Schema Definition Error if dfdl:setVariable appears on an element of complex type, or an
element reference to an element of complex type.

The ref property is a QName. That is, it may be qualified with a namespace prefix.

The syntax supports both a value attribute and the 'value' being specified by the element value.
Only one or the other may be present (otherwise it is a Schema Definition Error). To set the value
to "" (empty string), the value attribute syntax must be used, or the expression { "" } must be used
as the element value.

The value must match the type of the variable as specified by dfdl:defineVariable.
A dfdl:setVariable value expression may refer to the value of this element using a relative path
value ".". Use of relative path expressions is recommended wherever possible as this allows the
behavior of the parser to be more effectively scoped. However, this practice is not enforced and
there may be situations in which use of an absolute path is in fact necessary.

The expression must not contain forward references to elements which have not yet been
processed.
In normal processing, the value of an instance can only be set once using dfdl:setVariable. Attempting to set the value of the variable instance for a second time is a Schema Definition Error. In addition, if a reference to the variable's value has already occurred and returned a default or an externally supplied value, then no assignment (even a first one) can occur. An exception to this behavior occurs whenever the DFDL processor backtracks because it is processing multiple branches of a choice or as a result of speculative parsing. In this case the variable state is also rewound. See Section 9 DFDL Processing Introduction.

A dfdl:setVariable overrides any default value specified on either dfdl:defineVariable or dfdl:newVariableInstance, or externally.

The resolved set of annotations for an annotation point may contain multiple dfdl:setVariable statements. They must all be for unique variables (different name and/or namespace) and it is a Schema Definition Error otherwise. The order of execution is specified in Section 9.5 Evaluation Order for Statement Annotations.

There is no short form syntax for variable assignment.

7.7.3.1 Examples

```xml
<xs:element name="ds" type="xs:string">
  <xs:annotation><xs:appinfo source="http://www.ogf.org/dfdl/">
    <dfdl:setVariable ref="EDI:EDIFACT_DS" value="{.}" />
    <dfdl:setVariable ref="delimiter">{.}</dfdl:setVariable>
  </xs:appinfo></xs:annotation>
</xs:element>
```

In the above example, the element named "ds" contains the string to be used as the EDI:EDIFACT_DS delimiter at other places in the data, so the above defines the value of the EDI:EDIFACT_DS variable to take on the value of this element. The variable delimiter (in the default namespace) is also being assigned the same value using other syntax.
8 Property Scoping and DFDL Schema Checking

8.1 Property Scoping

8.1.1 Property Scoping Rules

This section describes the rules that govern the scope over which DFDL representation properties apply.

The scope of the representational properties on each of the component format annotations is given in Table 10 DFDL annotation scoping.

<table>
<thead>
<tr>
<th>Annotation Point</th>
<th>Property Scope</th>
</tr>
</thead>
<tbody>
<tr>
<td>Schema declaration</td>
<td>dfdl:format representation properties apply <em>lexically</em> as default properties over all components in the schema</td>
</tr>
<tr>
<td>Element declaration</td>
<td>dfdl:element properties apply locally</td>
</tr>
<tr>
<td>Element reference</td>
<td>dfdl:element properties apply locally</td>
</tr>
<tr>
<td>Simple type definition</td>
<td>dfdl:simpleType properties apply locally</td>
</tr>
<tr>
<td>Sequence</td>
<td>dfdl:sequence properties apply locally</td>
</tr>
<tr>
<td>Choice</td>
<td>dfdl:choice properties apply locally</td>
</tr>
<tr>
<td>Group reference</td>
<td>dfdl:group properties apply locally</td>
</tr>
</tbody>
</table>

Table 10 DFDL annotation scoping

Note: This table lists DFDL annotations on schema components. DFDL annotations can also be placed on other DFDL annotations, such as a dfdl:format within a dfdl:defineFormat, to provide a named reusable format definition. In this case the annotation applies only where the named format is referenced.

DFDL representation properties explicitly defined on annotations, other than a dfdl:format on an xs:schema declaration, apply locally to that component only. The explicitly defined properties are the combination of any defined locally on the annotation and any defined on the dfdl:defineFormat annotation referenced by a local dfdl:ref property. When a property is defined both locally and on the dfdl:defineFormat, the locally defined property takes precedence.

The dfdl:format annotation on the top level xs:schema declaration provides defaults for the DFDL representation properties at every DFDL-annotatable component contained in the schema document. They do not apply to any components in any included or imported schema document (these may have their own defaults).

8.1.2 Providing Defaults for DFDL properties

A dfdl:format annotation on the top level xs:schema declaration may provide defaults for some or all the DFDL representation properties at every annotation point within the schema document. The default properties may be specified in attribute or element form. (Short form is not allowed on the xs:schema element.)

The dfdl:ref property is not a representation property so no default can be set.

The dfdl:escapeSchemeRef property provides a default reference to a dfdl:defineEscapeScheme, the properties of dfdl:escapeScheme are not defaulted individually.

DFDL representation properties defined explicitly on a component apply only to that component and override the default value of that property provided by a default format specified by an xs:schema dfdl:format annotation.
The example below demonstrates the overriding of the encoding property. The value 'ASCII' is the default value for the title element, but then it is overridden by the locally defined utf-8 value for the encoding property, which takes precedence.

```xml
<xs:schema>
  <xs:annotation>
    <xs:appinfo source="http://www.ogf.org/dfdl/">
      <dfdl:format encoding="ASCII"/>
    </xs:appinfo>
  </xs:annotation>

  <xs:element name="book">
    <xs:complexType>
      <xs:sequence>
        <xs:element name="title" type="xs:string">
          <xs:annotation>
            <xs:appinfo source="http://www.ogf.org/dfdl/">
              <dfdl:element encoding="utf-8"/>
            </xs:appinfo>
          </xs:annotation>
        </xs:element>
        <xs:element name="pages" type="xs:int"/>
      </xs:sequence>
    </xs:complexType>
  </xs:element>
</xs:schema>
```

8.1.3 Combining DFDL Representation Properties from a dfdl:defineFormat

The DFDL representation properties contained in a referenced dfdl:defineFormat are combined with any DFDL representation properties defined locally on a construct as if they had been defined locally. If the same property is defined locally in and in the referenced dfdl:defineFormat then the local property takes precedence. The combined set of explicit DFDL properties has precedence over any defaults set by a dfdl:format on the xs:schema.

```xml
<xs:schema>
  <xs:annotation>
    <xs:appinfo source="http://www.ogf.org/dfdl/">
      <dfdl:defineFormat name='myFormat'>
        <dfdl:format encoding="ASCII"/>
      </dfdl:defineFormat>
    </xs:appinfo>
  </xs:annotation>

  <xs:element name="book">
    <xs:complexType>
      <xs:sequence>
        <xs:element name="title" type="xs:string">
          <xs:annotation>
            <xs:appinfo source="http://www.ogf.org/dfdl/">
              <dfdl:element ref='myFormat' encoding="UTF-8"/>
            </xs:appinfo>
          </xs:annotation>
        </xs:element>
        <xs:element name="pages" type="xs:int"/>
      </xs:sequence>
    </xs:complexType>
  </xs:element>
</xs:schema>
```

The example above demonstrates the overriding of an encoding property. The 'ASCII' format encoding from the 'myFormat' is overridden by the UTF-8 format encoding, which as a locally defined property takes precedence.
8.1.4 Combining DFDL Properties from References

The DFDL properties from the following types of reference are combined using the rules below:

- An xs:element and its referenced xs:simpleType restriction
- An xs:element reference and its referenced global xs:element
- An xs:group reference and an xs:sequence or xs:choice in its referenced global xs:group
- An xs:simpleType restriction and its base xs:simpleType restriction

Rules

1. Create (a) an empty working set of "explicit" properties, and (b) an empty working set of "default" properties.
2. Move to the innermost schema component in the chain of references.
3. Assemble its applicable "explicit" properties from its local dfdl:ref (if present) and its local properties (if present), the latter overriding the former (that is, local wins over referenced).
4. Combine these with the current working set of "explicit" properties. It is a Schema Definition Error if the same property appears twice. The result is a new working set of "explicit" properties.
5. Obtain applicable "default" properties from a dfdl:format annotation on the xs:schema that contains the component (if such annotation is present). Combine these with the current working set of "default" properties, the latter overriding the former (that is, inner wins). Result is a new working set of "default" properties.
6. Move to the schema component that references the current component and repeat starting at step 3. If there is no referencing component, carry out step 5 and then go to step 7.
7. Combine the resultant sets of properties. The "explicit" properties take priority, "defaults" only used when no "explicit" property is present. It is a Schema Definition Error if a required property is in neither the "explicit" nor the "default" working sets.

The "Applicable" properties are all the DFDL properties that apply to that schema component. For example, all the DFDL properties that apply to a particular xs:simpleType (as defined by Section 13).

```
<x:simpleType name="newType">
  <xs:annotation>
    <xs:appinfo source="http://www.ogf.org/dfdl/">
      <dfdl:simpleType alignment="16"/>
    </xs:appinfo>
  </xs:annotation>
  <xs:restriction base="xs:integer">
    <xs:maxInclusive value="10"/>
  </xs:restriction>
</xs:simpleType>

<x:element name="testElement1" type="newType">
  <xs:annotation>
    <xs:appinfo source="http://www.ogf.org/dfdl/">
      <dfdl:element representation="binary"/>
    </xs:appinfo>
  </xs:annotation>
</xs:element>
```

The locally defined dfdl:alignment property with value ‘16’ from the xs:simpleType ‘newType’ is combined with the locally defined dfdl:representation property with value ‘binary’ and applied to element 'testElement1'.

```
<x:simpleType name="otherNewType">
  <xs:annotation>
    <xs:appinfo source="http://www.ogf.org/dfdl/">
      <dfdl:simpleType alignment="64"/>
    </xs:appinfo>
  </xs:annotation>
</xs:simpleType>
```

The locally defined dfdl:alignment property with value ‘64’ is applied.
The locally defined dfdl:representation property with value 'binary' is combined with the locally defined dfdl:alignment property with value '64' from the xs:simpleType restriction 'otherNewType'.

The locally defined dfdl:alignment property with value '16' from the xs:simpleType 'newType' is combined with the locally defined dfdl:representation property with value 'binary' and locally defined dfdl:binaryNumberRep with a value of 'binary'

<?-- SCHEMA1 --><xs:schema targetNamespace="" xmlns:tns1="http://tns1">
  <xs:annotation>
    <xs:appinfo source="http://www.ogf.org/dfdl/">
      <dfdl:format encoding="ASCII" byteOrder="littleEndian"
          initiator="" terminator=""
          sequenceKind="ordered" />
    </xs:appinfo>
  </xs:annotation>
  <xsd:import namespace="http://tns2" schemaLocation="SCHEMA2.xsd"/>
The DFDL properties applied to the xs:sequence in xs:group "ggrp1" in SCHEMA2 when referenced from the group reference in SCHEMA1 are
1. dfdl:separator "," from the group reference in SCHEMA1
2. dfdl:separatorPosition "infix" from the group declaration in SCHEMA2
3. dfdl:encoding "UTF-8", dfdl:initiator "" from the default dfdl:format annotation in SCHEMA2
4. dfdl:terminator "" from the default dfdl:format annotation in SCHEMA1

8.2 DFDL Schema Checking

When the DFDL schema itself contains an error, it implies that the DFDL processor cannot process data because the DFDL schema is not meaningful. All conforming DFDL processors MUST detect all Schema Definition Errors and MUST issue appropriate diagnostic messages. The behavior of a DFDL processor after a Schema Definition Error is detected is out of scope for this specification. There is no centralized listing of the Schema Definition Errors; they are defined throughout this specification.

When a Schema Definition Error can be detected statically, that is given only the schema, it is desirable, though not required by the DFDL 1.0 specification, that diagnostic messages SHOULD be issued before any data are processed. However, because some representation properties may obtain their values from the data, not all Schema Definition Errors can be detected without reference to data so some Schema Definition Error diagnostics MAY of necessity be issued once data is being processed.

The expression language included within DFDL is strongly, statically type checkable. This means that type checking of expressions MAY be performed statically, that is, without processing data, and implementations are encouraged to perform this checking statically so that Static Type Errors (Schema Definition Errors having to do with type inconsistencies) can be detected before processing data.
8.2.1 **Schema Component Constraint: Unique Particle Attribution**

The term *particle* is used in XSD to refer to a schema component that can have dimension (XSD minOccurs and/or XSD maxOccurs) expressed on it. In DFDL only local element declarations and element references are particles.

A DFDL processor MUST implement the Schema Component Constraint: Unique Particle Attribution defined in *XML Schema Part 1: Structures* [XSDLV1] that applies to the DFDL schema subset.

Two elements **overlap** if

- They are both element declaration particles whose declarations have the same name and target namespace.

A schema violates the unique attribution constraint if it contains two particles which overlap and which either

- are both in the particles of a choice group.

or

- either describes adjacent information items in an xs:sequence and the first has XSD minOccurs less than XSD maxOccurs.

8.2.2 **Optional Checks and Warnings**

- A DFDL processor that only implements a DFDL parser does not have to perform Schema Definition Error checking for properties that are solely used when unparsing, though it is RECOMMENDED that it does so for portability reasons.

- A DFDL processor that does not implement some optional DFDL language features does not have to check properties or annotations needed by those optional language features but MUST issue a warning that an unrecognized property or annotation has been encountered.

- A DFDL processor MUST NOT check global element declarations nor type or group definitions as they may legitimately be incomplete due to properties intended to be supplied based on scoping rules and the context at the point of use. There are two exceptions to this, which MUST be checked:
  1. Global simple type definitions that are referenced by the dfdl:prefixLengthType property
  2. Global element declarations that are the document root.

Some situations suggest likely errors, but a DFDL processor cannot be certain. In these situations, a DFDL processor MAY issue warnings to assist a DFDL schema author in identifying likely errors. An important case of this is when the DFDL processor encounters a schema component and annotation where there are explicitly properties that are not relevant to the component as defined. Depending on the specifics of the component and property the DFDL processor MUST take certain actions. If the:

- Property is not applicable to the component's DFDL annotation.
  - Schema Definition Error. Example is dfdl:lengthKind on xs:sequence.

However, for these situations, the DFDL processor MAY take certain actions:

- Property is not applicable because of simple type.
  - Warning (optional). Example is dfdl:calendarPatternKind on xs:string.

- Property is not applicable because of another DFDL property setting.
  - Warning (optional). Example is dfdl:binaryNumberRep when dfdl:representation is text.

- Invalid value for a property that is unused or ignored.
  - Warning (optional). Example is dfdl:lengthKind is not 'explicit' but dfdl:length is an expression and that expression contains invalid syntax.
9 DFDL Processing Introduction

A DFDL Parser is an application or code library that takes as input:

- A DFDL annotated XML schema
- A data stream

It uses the DFDL schema description to interpret the data stream and realize the DFDL Information Set. If successful the data stream is said to be well-formed for the data format described by the DFDL Schema. The information set can then be written out (for example it could be realized as an XML or JSON text string) or it can be accessed by an application through an API (for example, a DOM-like tree could be created in memory for access by applications).

Symmetrically, there is a notion of a DFDL Unparser. The unparser works from an instance of the DFDL Information Set, a DFDL annotated schema and writes out to a target data stream in the appropriate representation formats.

Often both parser and unparser are implemented in the same body of software and so are not always distinguished. Collectively they are called a DFDL Processor. The parser and unparser MAY, of course, be different bodies of software. Conforming DFDL processors MAY implement only a parser, because the unparser is an optional feature of DFDL.

9.1 Parser Overview

The DFDL logical parser is a recursive-descent parser\(^\text{10}\) having guided, but potentially unbounded look ahead. A DFDL parser reads a specification (the DFDL schema) and it recursively walks down and up the schema as it processes the data. This is done in a manner consistent with the scoping of properties and variables described in Section 8 Property Scoping and DFDL Schema Checking.

Property Scoping

Property Scoping Rules

The unbounded look ahead means that there are situations where the parser MUST speculatively attempt to parse data where the occurrence of a Processing Error causes the parser to suppress the error, back out and make another attempt.

Implementations of DFDL MAY provide control mechanisms for limiting the speculative search behavior of DFDL parsers. The nature of these mechanisms is beyond the scope of the DFDL specification which defines the behavior of conforming parsers only on data that does not cause an implementation to reach such a control-mechanism limit. Any such control mechanisms MUST be documented by the implementation and are thus implementation-defined.

The logical parser recursively descends the DFDL schema beginning with the global element that is the document root. This is specified for the processor in an implementation-defined manner, see Section 20 External Control of the DFDL Processor. Depending on the kind of schema construct that is encountered and the DFDL annotations on it, and the pre-existing context, the parser performs specific parsing operations on the data stream. These parsing operations typically recognize and consume data from the stream and construct values in the logical model. For values of complex types and for arrays, these logical model values may incorporate values created by recursive parsing.

DFDL Implementations are free to use whatever techniques for parsing they wish so long as the semantics are equivalent to that of the speculative recursive-descent logical parser described in this specification. Implementations MUST distinguish the various kinds of errors (Schema Definition Error, Processing Error, etc.) no matter what time they are detected. Some implementations MAY not detect certain Schema Definition Errors until data are being parsed; however, they MUST still distinguish Schema Definition Errors from Processing Errors.

---

\(^\text{10}\) A "top-down" parser built from a set of mutually-recursive procedures or a non-recursive equivalent where each such procedure usually implements one of the productions of the grammar. Thus, the structure of the resulting program closely mirrors that of the grammar it recognizes. See [RDP].
9.1.1 Points of Uncertainty
A point of uncertainty occurs when there is more than one schema component that might be applied based on parsing up to the current point in the data stream.

Any one of the following constructs is a point of uncertainty:

- An xs:choice
- All xs:elements in an unordered xs:sequence (dfdl:sequenceKind\textsuperscript{11} is ‘unordered’)
- All xs:elements in an xs:sequence containing one or more dfdl:floating\textsuperscript{12} xs:elements

Any one of the following constructs is a potential point of uncertainty:

- An optional\textsuperscript{13} xs:element
- An array xs:element.

Examples of potential points of uncertainty are in Section 9.3.3 Resolving Points of Uncertainty.

9.1.2 Processing Error
If a DFDL schema contains no Schema Definition Errors, then there is the additional possibility of a Processing Error when processing data using a DFDL schema. A Processing Error occurs when parsing if the data does not conform to the format described by the schema, that is to say, the data is not well-formed relative to the schema. A Processing Error occurs when unparsing when the incoming Infoset does not conform to the logical structure described by the schema.

Processing Errors interact with the schema’s points of uncertainty. When a DFDL parser encounters a Processing Error, then that error is said to be suppressed by a point of uncertainty if there is another schema component that can be selected by the parsing algorithm. The details of the DFDL parsing algorithm are described in Section 9.3.

Processing Errors MUST be able to be suppressed by a point of uncertainty. See Section 9.3.3. Note that unlike Processing Errors, Schema Definition Errors cannot be suppressed by points of uncertainty when parsing data. That is, a Schema Definition Error is fatal. It does not trigger search or backtracking to find alternative ways to parse the data.

9.1.3 Recoverable Error
This error type is used with the dfdl:assert annotation when parsing to permit the checking of physical format constraints without terminating a parse. For example, some formats have redundancy by having known lengths, as well as delimiters. A Recoverable Error can be issued, using an assert to check a physical length constraint when property lengthKind is ‘delimited’.

Recoverable Errors are independent of validation, and when resolving points of uncertainty, Recoverable Errors are ignored.

9.2 DFDL Data Syntax Grammar
Data in a format describable via a DFDL schema obeys the grammar given here. A given DFDL schema is read by the DFDL processor to provide specific meaning to the terminals and decisions in this grammar.

The bits of the data are divided into two broad categories:

1. Content
2. Framing

The content is the bits of data that are interpreted to compute a logical value.

\textsuperscript{11} For dfdl:sequenceKind, see Section 14 Sequence Groups.
\textsuperscript{12} For dfdl:floating elements, see Section 14.4 Floating Elements.
\textsuperscript{13} For optional and array elements, see Section 16 Properties for Array Elements and Optional Elements.
Framing is the term used to describe the delimiters, length fields, and other parts of the data stream which are present and may be necessary to determine the length or position of the content of DFDL Infoset items.

Note that sometimes the framing is not strictly necessary for parsing, but adds useful redundancy to the data format, allowing corrupt data to be more robustly detected, and sometimes the framing adds human readability to the data format.

In the grammar tables below, the terminal symbols are shown in bold italic font.

Table 11 DFDL Grammar Productions
XML Schema and DFDL properties are used to control constraints on the terminals of the above grammar, as well as repetition (the "*" operator), and alternatives (the "|" operator). For a given set of XML Schema and DFDL properties, and prior data, any terminal may be allowed to be length zero, to contain specific data, or to contain a variety of different admissible data. Some definitions are needed to cover the range of representations that are possible in the data stream for an occurrence of an element. The representations are:

- Nil Representation
- Empty Representation
- Normal Representation
- Absent Representation

These additional concepts are also defined:

- Zero-Length Representation
- Missing
These definitions are with respect to the grammar above, and they do reference some DFDL properties necessary for their definitions. These properties are defined in Sections 11 and beyond.

Some examples follow the definitions.

9.2.1 Nil Representation

An element occurrence has a *nil representation* if the element declaration has XSD nillable property 'true' and the occurrence either:

- conforms to the grammar for SimpleNilLiteralElementRep or ComplexNilLiteralElementRep. Specifically, the **NilElementInitiator** and **NilElementTerminator** regions must be conformant with property dfdl:nilValueDelimiterPolicy. (If non-conformant it is not a Processing Error and the representation is not nil).
- conforms to the grammar for SimpleNormalRep and its SimpleLogicalValue is **NilLogicalValue**.

The LeadingAlignment, TrailingAlignment, PrefixLength regions may be present.

9.2.2 Empty Representation

An element occurrence has an *empty representation* if the occurrence does not have a nil representation and it conforms to the grammar for SimpleEmptyElementRep or ComplexEmptyElementRep. Specifically, the **EmptyElementInitiator** and **EmptyElementTerminator** regions must be conformant with dfdl:emptyValueDelimiterPolicy and the occurrence's SimpleContent or ComplexContent region in the data must be of length zero. (If non-conformant it is not a Processing Error and the representation is not empty).

LeadingAlignment, TrailingAlignment, PrefixLength regions may be present.

The *empty representation* is special in DFDL because when parsing it is used to determine when default values are created in the Infoset. The empty representation can require initiators or terminators be present to enable data formats which explicitly distinguish occurrences with empty string/hexBinary values from occurrences that are missing or are absent. See Section 9.4 Element Defaults below about default values. Hence, the empty representation might not be zero-length. it may require specific non-zero-length syntax in the data stream.

The empty representation is not possible for fixed-length elements with a non-zero length.

9.2.3 Normal Representation

An element occurrence has a normal representation if the occurrence does not have the nil representation or the empty representation and it conforms to the grammar for SimpleNormalRep or ComplexNormalRep.

Note that it is possible for the normal representation to be of zero length, but this can only happen when zero-length is not the nil nor empty representation, and the simple type is xs:string or xs:hexBinary. For all other simple types, the normal representation cannot be zero length.

9.2.4 Absent Representation

Often, it is possible to know the location where an element or group's representation would be in the data based on the delimiters of an enclosing group. (An example: if there are adjacent delimiters of an enclosing sequence.) When this location in the data, which is of zero length, cannot be a nil, empty, or normal representation, then it is said to have *absent representation*, or "the representation is absent".

More formally, an element occurrence has an absent representation if the occurrence does not have a nil or empty or normal representation, and it conforms to the grammar for AbsentElementRep. Specifically, the occurrence's representation in the data stream must be of

---

14 For dfdl:nilValueDelimiterPolicy, see Section 13.16 Properties for Nillable Elements.
15 For dfdl:emptyValueDelimiterPolicy, see Section 12.2 Properties for Specifying Delimiters.
length zero. Consequently, the Initiator, Terminator, LeadingAlignment, TrailingAlignment, PrefixLength regions must not be present.

As an example of an absent representation: during unparsing, if an optional element does not have an item in the Infoset then nothing is output. However, if a separator of an enclosing structure is subsequently output as the immediate next thing, then a subsequent parse of the element may return a representation of length zero. If this happens, and this zero-length representation does not conform to any of the nil representation, the empty representation, or the normal representation, then it is the absent representation, and it behaves as if the element occurrence is 'missing'. (The term 'missing' is defined below.)

9.2.5 Zero-length Representation

The term zero-length representation is used to describe the situations where any of the above representations turn out to be of length zero due to specific combinations of data type and format properties:

- The nil representation can be a zero-length representation if dfdl:nilValue is ‘%ES;’ or ‘%WSP*;’ appearing on its own as a literal nil value and there is no framing or framing is suppressed by dfdl:nilValueDelimiterPolicy.
- The empty representation can be a zero-length representation if there is no framing or framing is suppressed by dfdl:emptyValueDelimiterPolicy.
- The normal representation can be a zero-length representation if the type is xs:string or xs:hexBinary and there is no framing.
- The absent representation always has a zero-length representation.

If the nil representation may be zero-length, then the absent representation cannot occur because zero-length is interpreted as nil representation.

If the nil representation may not be zero length, but the empty representation is zero-length, then the absent representation cannot occur because zero-length is interpreted as the empty representation.

If the nil and empty representations cannot be zero-length, but the normal representation may be zero length then the absent representation cannot occur because zero length is interpreted as a normal representation.

If the nil representation may not be zero-length, the empty representation may not be zero-length, and the normal representation may not be zero-length, then a zero-length representation is the absent representation, or "is absent".

9.2.6 Missing

When parsing, an element occurrence is missing if it does not have nil, empty, or normal representations, or it has the absent representation.

When parsing, the term missing really covers two situations. First, it subsumes absent representation. Secondly it applies when an element does not have a representation at all in the data stream, that is, when there are insufficient constructs in the data stream to determine the location of the representation of the element; hence, none of the concepts above apply. This is made clearer in the examples below. If an element occurrence is missing when parsing, no item is ever added to the Infoset.

When unparsing, an element occurrence is missing if there is no item in the Infoset. For a required element occurrence, it is this condition that can trigger the creation of a default value in the augmented Infoset. See Section 9.4 Element Defaults below about default values. For an optional element occurrence, no item is ever added to the augmented Infoset nor any representation ever output in the data stream.

9.2.7 Examples of Missing and Empty Representation

The following examples illustrate missing and empty representation.

```xml
<xs:sequence dfdl:separator=""," dfdl:terminator="@
    dfdl:separatorSuppressionPolicy="trailingEmpty" ...>
    <xs:element name="A" type="xs:string"
```
In data stream 'aaa,ß' element B has the empty representation, and element C does not have a representation so is missing.

In data stream 'A:aaaa,C:cccc' element B does not have a representation at all, so is missing.

In data stream 'A:aaaa,B:,C:cccc' element B has the empty representation. The format definition requires element B to have its initiator in order to indicate the empty representation.

In the data stream 'A:aaaa,,C:cccc' element B has the absent representation, because the processor is able to tell where element B would appear, but the syntax there does not contain the needed initiator delimiter; hence, it does not satisfy any of nil, empty, or normal representation. Since the processor knows its location, and the data stream there (between the two separators) is zero-length, it is the absent representation, and so is missing.

9.3 Parsing Algorithm

A DFDL parser proceeds by determining the existence of occurrences of schema components. It does this by examining the data and the schema, to:

a) Establish representation
b) Resolve points of uncertainty

These two activities are defined below. They are mutually recursive in the expected way as a DFDL schema is a recursive nest of schema components.
The parsing algorithm described here has many aspects which depend on the definitions of numerous DFDL properties. The properties are defined in sections 10 and beyond. Establishing the representation of an occurrence of a schema component and resolving points of uncertainty involve the concepts of known-to-exist and known-not-to-exist.

9.3.1 Known-to-exist and Known-not-to-exist

9.3.1.1 Known-to-exist
An occurrence of a schema component is said to be known-to-exist when any of these positive determinations hold:

1. There is a dfdl:discriminator\(^{16}\) applying to the component and its expression evaluates to true or regular expression pattern matches.
2. The component is a direct child of an xs:sequence or xs:choice with dfdl:initiatedContent\(^{17}\) 'yes' and a dfdl:initiator defined for the component is found.
3. The component is a direct child of an xs:choice with dfdl:choiceDispatchKey\(^{18}\) and the result of the dfdl:choiceDispatchKey expression matches one of the dfdl:choiceBranchKey property values of the child.

If none of those hold because they are not applicable then the occurrence is still known-to-exist if ALL of the following hold, and no Processing Error occurs during their determination:

1. When there are dfdl:assert\(^{19}\) statements with failureType 'processingError' on the component, all their expressions evaluate to true or their regular expression patterns match.
2. It has nil, empty, or normal representation.
3. When it has normal representation the content of the representation is convertible to the element type without error.

Note that Validation Errors or Recoverable Errors do not prevent determination that a component is known-to-exist.

9.3.1.2 Processing Error After Determining Known-to-exist
Note that it is possible for an occurrence of a schema component to be known-to-exist due to a positive discrimination, but then subsequently a Processing Error occurs when evaluating a statement annotation such as a dfdl:assert or a dfdl:setVariable, or a Processing Error occurs when determining the representation, or in the case of normal representation and simple type, when converting that representation's content into a value of the type. This Processing Error does not change the fact that the schema component was determined to be known-to-exist. This is important in the discussion in Section 9.3.3, Resolving Points of Uncertainty below.

9.3.1.3 Known-not-to-exist
An occurrence of a schema component is known-not-to-exist when any of these negative determinations holds:

1. There is a dfdl:discriminator applying to the component and its expression evaluates to false or regular expression pattern fails to match, or a Processing Error occurs while processing the dfdl:discriminator.
2. The component is a direct child of an xs:sequence or xs:choice with dfdl:initiatedContent 'yes' and an initiator defined for the component is not found.

---

\(^{16}\) DFDL discriminators are described in Section: 7.6 The dfdl:discriminator Statement Annotation Element.
\(^{17}\) For dfdl:initiator and dfdl:initiatedContent, see Section 12.2 Properties for Specifying Delimiters.
\(^{18}\) For dfdl:choiceDispatchKey and dfdl:choiceBranchKey, see Section 15.1.2 Resolving Choices via Direct Dispatch.
\(^{19}\) DFDL asserts are described in Section 7.5 The dfdl:assert Statement Annotation Element.
3. The component is a direct child of an xs:choice with dfdl:choiceDispatchKey and the result of the dfdl:choiceDispatchKey expression does not match any of the dfdl:choiceBranchKey property values of the child.

4. The component is an element of complex type, the model group of which is a sequence group, and the sequence group is known not to exist.

If none of those hold because they are not applicable, then a schema component is known-not-to-exist when any of the following hold:

1. The occurrence is missing
2. There is a dfdl:assert with failureType 'processingError' on the component and its expression evaluates to false or its regular expression pattern fails to match, or a Processing Error occurs while processing the dfdl:assert.
3. A Processing Error occurs when parsing the component. Processing Errors include, but are not limited to, inability to identify any of nil, empty, normal or absent representations, or failure to convert a value to the built-in logical type.

Note that Validation Errors or Recoverable Errors do not cause a component to be known-not-to-exist.

Note: based on the above, when processing a sequence for which a separator is defined, the presence of a match in the data for the separator is not sufficient to cause the parser to determine that an associated component is known-to-exist. See Section 14.2 Sequence Groups with Separators for details.

9.3.2 Establishing Representation

Unless an element occurrence is known-not-to-exist, the parsing algorithm establishes if it has the nil, empty, normal, or absent representation.

The first step is to see if the SimpleContent or ComplexContent region is of length zero as a first approximation. This is dfdl:lengthKind dependent.

- explicit => length is zero (either fixed or from expression evaluation)
- prefixed => length given by the prefix is zero
- implicit (simple) => length is zero
- implicit (complex) => not possible.
- delimited => length is zero (in scope delimiter is immediately encountered)
- pattern => pattern returns zero length match
- endOfParent => already positioned at parent's end so length is zero

9.3.2.1 Simple element

If the result is length zero as described above, the representation is then established by checking, in order, for:

1. nil representation (if %ES; or %WSP*; on its own is a literal nil value).
2. empty representation.
3. normal representation (xs:string or xs:hexBinary only)
4. absent representation (if none of the prior representations apply).

If the result is not length zero, the representation is then established by checking, in order, for:

1. nil representation (as a literal nil value)
2. nil representation (as a logical nil value)
3. normal representation

---

This is a corner case that only happens when type is xs:string or xs:hexBinary and the maxLength facet is 0. Such an element can only be of length 0.
9.3.2.2 Complex element

If the result is length zero as described above, the representation is then established by checking for:

- nil representation (if %ES; is a literal nil value).\(^{21}\)

To establish any other representations requires that the parser descends into the complex type for the element, and returns successfully (that is, no unsuppressed Processing Error occurs). If the result is zero bits consumed, the representation is then established by checking, in order, for:

1. empty representation.
2. absent representation (if none of the prior representations apply).

Otherwise the element has normal representation.

Note: The DFDL parser SHALL NOT recursively parse the schema components inside a complex element when it has already established that the element occurrence is missing.\(^{22}\)

9.3.3 Resolving Points of Uncertainty

A point of uncertainty occurs when there is more than one schema component that might be applied at the current point in the data stream. Points of uncertainty can be nested.

The parser resolves these points of uncertainty by way of a set of construct-specific rules given below along with determining whether schema components are known-to-exist or known-not-to-exist. For some of these constructs, whether there is an actual point of uncertainty depends on the representation of the constructs in the data.

An xs:choice is always a point of uncertainty. It is resolved sequentially, or by direct dispatch. Sequential choice resolution occurs by parsing each choice branch in schema definition order until one is known-to-exist. It is a Processing Error if none of the choice branches are known-to-exist. Direct-dispatch choice resolution occurs by matching the value of the dfdl:choiceDispatchKey property to the value of one of the dfdl:choiceBranchKey property values of one of the choice branches. It is a Processing Error if none of the choice branches have a matching value in their dfdl:choiceBranchKey property.

An element in an unordered xs:sequence is always a point of uncertainty. It is resolved by parsing for the child components of the sequence in schema definition order at each point in the data stream where a component can exist until the required number of occurrences of each child component is known-to-exist or the sequence is terminated by delimiters or specified length.

An element in a sequence with one or more floating elements is always a point of uncertainty. It is resolved by parsing for the expected element at that point in the data stream. If the expected element is known-not-to-exist then an occurrence of each floating element is parsed in schema definition order.

When parsing an array or optional element, points of uncertainty only occur for certain values of dfdl:occursCountKind, as follows:

<table>
<thead>
<tr>
<th>dfdl:occursCountKind</th>
<th>Details of Point of Uncertainty</th>
</tr>
</thead>
<tbody>
<tr>
<td>fixed</td>
<td>No point of uncertainty (XSD maxOccurs occurrences expected).</td>
</tr>
<tr>
<td>implicit</td>
<td>A point of uncertainty exists after XSD minOccurs occurrences are found and until XSD maxOccurs occurrences are found.</td>
</tr>
<tr>
<td>parsed</td>
<td>A point of uncertainty exists for all occurrences</td>
</tr>
</tbody>
</table>

---

\(^{21}\) It is a Schema Definition Error if a complex element has XSD nillable ‘true’ and dfdl:lengthKind ‘implicit’.

\(^{22}\) The rationale for this is that otherwise this could give rise to misleading error messages where the parser reported that required child elements were missing required occurrences. (This is consistent with XML Schema validation, where if a required element is missing, it gets reported as such, and there is nothing reported about its children).

\(^{23}\) Property dfdl:occursCountKind is defined in Section 16.1.
expression | No point of uncertainty (dfdl:occursCount\textsuperscript{24} values are expected)
stopValue | No point of uncertainty (The stop value must always be present, even when XSD minOccurs is 0).

Table 12: Points of Uncertainty and dfdl:occursCountKind

An optional element point of uncertainty is resolved by parsing the element until it is either known-to-exist or known-not-to-exist. Whether an optional element is an actual point of uncertainty depends on property dfdl:occursCountKind as described above.

For an array element, the point of uncertainty is resolved for each occurrence separately by parsing the occurrence until it is either known-to-exist or known-not-to-exist.

9.3.3.1 Nested Points of Uncertainty

A point of uncertainty can be resolved because a schema component has been determined to be known-to-exist due to positive discrimination. In that case, if a subsequent Processing Error occurs when completing the parsing of that schema component this causes the next enclosing schema component surrounding this point of uncertainty to be determined to be known-not-to-exist.

For example, when parsing an element occurrence for an array with a variable number of occurrences, a positive discrimination tells the parser that the currently-being-parsed occurrence is known-to-exist. If a subsequent Processing Error occurs while completing the parsing of this occurrence, then the entire array is then known-not-to-exist.

Another example is a choice. If a discriminator resolves the choice point of uncertainty to the first of the choice’s alternatives, a subsequent Processing Error causes the entire choice construct to be determined to be known-not-to-exist.

This causes the next enclosing point of uncertainty to try the next possible alternative, or if there isn’t one, causes an unsuppressed Processing Error.

The behavior of a DFDL processor on an unsuppressed Processing Error is not specified, but it is allowable for implementations to abort further parsing. Any other behavior is implementation-defined.

A discriminator always resolves the nearest enclosing point of uncertainty that is unresolved. If more than one discriminator is evaluated, the first resolves the nearest enclosing point of uncertainty, the second the next nearest enclosing point of uncertainty, and so on.

9.4 Element Defaults

A DFDL processor can create element defaults in the Infoset for both simple and complex elements. This happens quite differently for parsing and unparsing as is explained in this section.

9.4.1 Definitions

9.4.1.1 Default Value

A simple element has a default value if any of these are true:

1. The XSD default property exists. The default value is the XSD default property's value.
2. The XSD fixed\textsuperscript{25} property exists. The default value is the XSD fixed property's value.
3. The element has XSD nillable is ‘true’ and dfdl:useNilForDefault\textsuperscript{26} is ‘yes’. The corresponding Infoset item has the [nilled] member true, and the [dataValue] member has no value.

\textsuperscript{24} Property dfdl:occursCount is defined in Section 16.

\textsuperscript{25} For the XSD fixed property see Section 5.3.7.

\textsuperscript{26} For dfdl:useNilForDefault see Section 13.16.
9.4.1.2  Required/Optional Occurrence

An occurrence of an element with an index less than or equal to XSD minOccurs is said to be a required occurrence.

An occurrence of an element with an index greater than XSD minOccurs is said to be an optional occurrence.

9.4.2  Element Defaults When Parsing

If empty representation is established when parsing, the possibility of applying an element default arises. Essentially, if a required occurrence of an element has empty representation, then an element default is applied if present, though there are a couple of variations on this rule. Remember that in order to have established empty representation, the occurrence must be compliant with the dfdl:emptyValueDelimiterPolicy for the element, and for a complex element the parser must have descended into the type and returned with no unsuppressed Processing Error.

The rules for applying element defaults are not dependent on dfdl:occursCountKind. However, if a required occurrence does not produce an item in the Infoset after the rules have been applied, then whether it is a Processing Error or a Validation Error (if validation is enabled) does depend on dfdl:occursCountKind (see Section 16.1 dfdl:occursCountKind property).

The sections below indicate when an item is added to the Infoset, and whether it has a default or other value. If there is no Processing Error then regardless of whether an item is added to the Infoset or not, any side-effects due to dfdl:discriminator statements evaluating to true, or dfdl:setVariable statements, are retained.

Assuming the empty representation has been established, there are three cases to consider:

- Simple element (not type xs:string or xs:hexBinary)
- Simple element (type xs:string or xs:hexBinary)
- Complex element

Each is described in a section below.

9.4.2.1  Simple element (not xs:string and not xs:hexBinary)

Required occurrence: If the element has a default value then an item is added to the Infoset using the default value, otherwise nothing is added to the Infoset.

Optional occurrence: Nothing is added to the Infoset.

9.4.2.2  Simple element (xs:string or xs:hexBinary)

Required occurrence: If the element has a default value then an item is added to the Infoset using the default value, otherwise an item is added to the Infoset using empty string (type xs:string) or empty hexBinary (type xs:hexBinary) as the value.

Optional occurrence: if dfdl:emptyValueDelimiterPolicy is applicable and is not 'none', then an item is added to the Infoset using empty string (type xs:string) or empty hexBinary (type xs:hexBinary) as the value, otherwise nothing is added to the Infoset.

Note: To prevent unwanted empty strings or empty hexBinary values from being added to the Infoset, use XSD minLength > '0' and a dfdl:assert that uses the dfdl:checkConstraints() function, to raise a Processing Error.

9.4.2.3  Complex element

Required occurrence: An item is added to the Infoset.

Optional occurrence: if dfdl:emptyValueDelimiterPolicy is applicable and is not 'none', then an item is added to the Infoset, otherwise nothing is added to the Infoset.

---

27 If other than 'none', either an initiator, terminator or both must have been found in the data stream.

28 For dfdl:checkConstraints function see Section 18.5.3

29 If other than 'none', either an initiator, terminator or both must have been found in the data stream.
For both required and optional occurrences, the parser, by recursive descent, may create the Infoset item and a single child Infoset item. This can occur when:

1. the first child element of the complex type is a required simple element, then an empty string (type xs:string), empty hexBinary (type xs:hexBinary), or default value is also added to the Infoset.
2. the first child element of the complex type is a required complex element, then an item is added to the Infoset (which may itself have a child via (1))

9.4.2.4 Example: Complex Optional Empty Element Not Added to Infoset

Below is an example where an optional complex element with empty representation has nothing added to the infoset. consider the following:

```xml
<xs:sequence dfdl:separator="|"> <!-- sequence S0 -->
...prior schema components ...
<xs:element name="E1" minOccurs="0" dfdl:lengthKind="delimited" dfdl:occursCountKind="implicit">
<xs:complexType>
<xs:sequence dfdl:separator=";">
<!-- sequence S1 -->
<xs:element name="E2" type="xs:string" dfdl:lengthKind="delimited"/>
... other optional content ...
</xs:sequence>
</xs:complexType>
</xs:element>
...
</xs:sequence>
```

In the above there is a sequence S0 with a separator that contains among other content an optional, non-niliable, non-initiated, non-terminated element E1 of complex type. The content of the E1 type is a sequence S1 with a different separator and the first child is a required, non-initiated, non-terminated element E2 of type xs:string. The dfdl:lengthKind of both E1 and E2 is 'delimited'.

Now consider a data stream '...||...' which has two adjacent S0 separators, and where the parser has successfully parsed the schema components prior to E1 within S0, which is what the "..." prior to the two separators represents. That prior parse is delimited by the first S0 "|" separator, and E1's representation begins immediately after that first S0 separator.

The representation of E1 has zero length because of these two adjacent S0 separators. On processing E1, the parser establishes a point of uncertainty with the data stream positioned after the first S0 separator. The parser then descends into E1's complex type to process E2. It scans for in-scope delimiters and immediately encounters the second S0 separator. E2 has the empty representation, so E1 is added to the Infoset along with a value of empty string for E2. All other content of S1 is missing, so the parser returns from the descent into E1 with this temporary Infoset (illustrated as XML):

```xml
<E1>
  <E2/></E2>
</E1>
```

Upon this successful parse of E1, it is therefore known-to-exist. However, because the position in the data has not changed, E1 therefore has the empty representation. Because E1 is empty and optional (it has XSD minOccurs='0') and dfdl:emptyValueDelimiterPolicy does not apply, it is not added to the Infoset, and the temporary Infoset item for E1 containing E2 is discarded.

9.4.2.5 Example: Complex Optional Empty Element with Delimiters

This example is similar, but the E1 element has a few additional DFDL properties highlighted in bold below:

```xml
<xs:sequence dfdl:separator="|"> <!-- sequence S0 -->
...prior schema components ...
```
<xs:element name="E1" minOccurs="0"
        dfdl:initiator="(
        dfdl:terminator=")
        dfdl:emptyValueDelimiterPolicy="both"
        dfdl:lengthKind="delimited"
        dfdl:occursCountKind="implicit">
    <xs:complexType>
        <xs:sequence dfdl:separator=";">
            <!--sequence S1-->
            <xs:element name="E2" type="xs:string" dfdl:lengthKind="delimited"/>
            ... other optional content ...
        </xs:sequence>
    </xs:complexType>
</xs:element>

This changes the definition of element E1 to have an empty representation only if the initiator and terminator are present in the data stream.

Consider has the same data stream ‘...||...’ where there are two adjacent S0 separators. In this case the representation of E1 does not match the empty representation, because the initiator and terminator are not present as the dfdl:emptyValueDelimiterPolicy requires. It also does not have the normal representation, again as the initiator and terminator are not present. E1’s representation is absent. Hence, nothing is added to the infoset.

However, if the data stream ‘...()...’ is encountered, there are two S0 separators, but between them there are the initiator and terminator of element E1. This satisfies the requirements for the empty representation, but it is not zero length. The recursive parse of E1’s complex type constructs these elements (illustrated as XML):

```
<E1>
  <E2/></E2>
</E1>
```

These elements for E1 with E2 child would be added to the infoset.

### 9.4.3 Element Defaults When Unparsing

If an element is missing from the Infoset when unparsing, the possibility of applying an element default arises. Essentially if a required occurrence of an element is missing, then an element default is applied if present, and the resulting item is added to the augmented Infoset (See Section 9.7)

The rules for applying element defaults are not dependent on dfdl:occursCountKind. However if a required occurrence does not produce an item in the augmented Infoset after the rules have been applied then whether it is a Processing Error or a Validation Error (if enabled) is dependent on dfdl:occursCountKind (see Section 16.1 dfdl:occursCountKind property).

There are two cases to consider.

#### 9.4.3.1 Simple element

Required occurrence: If an element has a default value then an item is added to the augmented Infoset using the default value, otherwise nothing is added.

Optional occurrence: Nothing is added to the augmented Infoset.

#### 9.4.3.2 Complex element

Required occurrence: An item is added to the augmented Infoset as specified below.

Optional occurrence: An item is added to the augmented Infoset.

For a required occurrence, the unparses descends into the complex type:

For a sequence, each child element is examined in schema order and the rules for simple and complex elements applied (recursively). The lack of a default may give rise to a Processing Error, as described above.
For a choice, each branch is examined in schema order and the above rules applied recursively to the branch. The lack of a default may give rise to a Processing Error, as described above, and if so the error is suppressed and the next branch is tried, otherwise that branch is selected. It is a Processing Error if no choice branch is ultimately selected. If no choice branch is selected, then there must be a choice branch with no required elements, and the first such branch would be selected.

9.5 Evaluation Order for Statement Annotations

Given a component of a DFDL schema, there is a resolved set of annotations for it. Of these, some are statement annotations and the order of their evaluation relative to the actual processing of the schema component itself (parsing or unparsing via its format annotations) is as defined in the ordered lists below.

For elements and element references:
1. dfdl:discriminator or dfdl:assert(s) with testKind 'pattern' (parsing only)
2. dfdl:element following property scoping rules, which includes establishing representation as described in Section 9.3.2 and conversion to the element type for simple types
3. dfdl:setVariable(s) - in lexical order, innermost schema component first
4. dfdl:discriminator or dfdl:assert(s) with testKind 'expression' (parsing only)

For sequences, choices and group references:
1. dfdl:discriminator or dfdl:assert(s) with testKind 'pattern' (parsing only)
2. dfdl:newVariableInstance(s) - in lexical order, innermost schema component first
3. dfdl:setVariable(s) - in lexical order, innermost schema component first
4. dfdl:sequence or dfdl:choice or dfdl:group following property scoping rules and evaluating any property expressions (corresponds to ComplexContent grammar region)
5. dfdl:discriminator or dfdl:assert(s) with testKind 'expression' (parsing only)

The dfdl:setVariable annotations at any one annotation point of the schema are always executed in lexical order. However, dfdl:setVariable annotations can also be found in different annotation points that are combined into the resolved set of annotations for one schema component. In this case, the order of execution of the dfdl:setVariable statements from any one annotation point remains lexical. The order of execution of the dfdl:setVariable annotations different annotation points follows the principle of innermost first, meaning that a schema component that references another schema component has its dfdl:setVariable statements executed after those of the referenced schema component. For example, if an element reference and an element declaration both have dfdl:setVariable statements, then those on the element declaration execute before those on the element reference. Similarly, dfdl:setVariable statements on a base simple type execute before those of a simple type derived from it. The dfdl:setVariable statements on a simple type execute before those on an element having that simple type (whether that type is by reference, or when the simple type is lexically nested within the element declaration). The dfdl:setVariable statements on the sequence or choice within a global group definition execute before those on a group reference.

The dfdl:newVariableInstance annotations at any one annotation point of the schema are always executed in lexical order. However, dfdl:newVariableInstance annotations can also be found in different annotation points that are combined into the resolved set of annotations for one schema component. In this case, the order of execution of the dfdl:newVariableInstance statements from any one annotation point remains lexical. The order of execution of the dfdl:newVariableInstance annotations different annotation points follows the principle of innermost first, meaning that a schema component that contains or references another schema component has its dfdl:newVariableInstance statements executed after those of the contained or referenced schema component. For example, if a group reference and the sequence or choice group of a group definition both have dfdl:newVariableInstance statements, then those on the global group definition execute before those on the group reference.
9.5.1 **Asserts and Discriminators with testKind 'expression'**

Implementations are free to optimize by recognizing and executing discriminators or asserts with testKind 'expression' earlier so long as the resulting behavior is consistent with what results from the description above.

9.5.2 **Discriminators with testKind 'expression'**

When parsing, an attempt to evaluate a discriminator MUST be made even if preceding statements or the parse of the schema component ended in a Processing Error.

This is because a discriminator's expression can evaluate to true thereby resolving a point of uncertainty even if the complete parsing of the construct ultimately caused a Processing Error.

Such discriminator evaluation has access to the DFDL Infoset of the attempted parse as it existed immediately before detecting the parse failure. Attempts to reference parts of the DFDL Infoset that do not exist are Processing Errors.

9.5.3 **Elements and setVariable**

The resolved set of dfdl:setVariable statements for an element are executed after the parsing of the element. This contrasts with the resolved set of dfdl:setVariable statements for a group which are executed before the parsing of the group. (Note that dfdl:setVariable for an element is only allowed on elements of simple type per Section 7.7.3.)

For elements, this implies that these variables are set after the evaluation of expressions corresponding to any computed DFDL properties for that element, and so the variables may not be referenced from expressions that compute these DFDL properties.

That is, if an expression is used to provide the value of a property (such as dfdl:terminator or dfdl:byteOrder), the evaluation of that property expression occurs before any dfdl:setVariable annotation from the resolved set of annotations for that element are executed; hence, the expression providing the value of the property may not reference the variable. Schema authors can insert sequences to provide more precise control over when variables are set.

9.5.4 **Controlling the Order of Statement Evaluation**

Schema authors can insert xs:sequence constructs to control the timing of evaluation of statements more precisely. For example:

```xml
<xs:sequence dfdl:separator="","">
    ...  
    <xs:element ref="a" .../> 
    <xs:sequence>
        <xs:sequence>
                <dfdl:assert test="{test expression}" />
            </xs:appinfo></xs:annotation>
        </xs:sequence>
    </xs:sequence>
    <xs:element ref="b" .../>
    <xs:sequence>
        ... 
    </xs:sequence>
</xs:sequence>
```

In the above, the assert test expression is evaluated after parsing element 'a', and before parsing element "b". The use of two nested interior sequences surrounding element 'b' in this manner ensures that the outermost sequence's separator usage is not disrupted.

9.6 **Validation**

Logical validation checks are constraints expressed in XSD, and they apply to the logical values of the Infoset. Hence, parsing MUST successfully construct the Infoset before validation checks can be performed. This implies that DFDL Validation Errors cannot affect the parsing of data. DFDL processors MAY provide both validating and non-validating behaviors on either or both of parse and unparse. (A DFDL implementation could support validate on parse, but not support it on unparse and still be considered conforming.)
Validation on unparsing takes place on the augmented Infoset that is created by the unparsers as a side-effect of creating the output data stream. Validation errors do not affect unparsers behavior. When resolving points of uncertainty (during parsing), Validation Errors are ignored.

The way a Validation Error is presented to the execution context of a DFDL processor is not specified by the DFDL specification. The validity of an element is recorded in the DFDL Infoset, see Section 4 The DFDL Information Set (Infoset).

The following DFDL schema constructs are allowed in DFDL and are checked if applicable when validating:

1. XSD pattern facet
2. XSD minLength, maxLength
3. XSD minInclusive, minExclusive, maxInclusive, maxExclusive
4. XSD enumeration
5. XSD maxOccurs

Note that validation is distinct from the checking of DFDL assert or discriminator predicates. Both DFDL asserts and discriminators are essential to parsing and are evaluated irrespective of whether validation is enabled or disabled.

There is also a function dfdl:checkConstraints available in the DFDL Expression language. This can be used to explicitly include checking of the XSD constructs as part of parsing a specific element. Such checking is part of parsing and does not create Validation Errors. See Section 18.5.3 DFDL Functions for details.

9.7 Unparser Infoset Augmentation Algorithm

As unparsing progresses and fills in these defaultable and calculated elements, these new item values augment the Infoset, that is, make it bigger.

The unparsing algorithm fills in default values for required elements that are not present, and computes calculated elements by use of the dfdl:outputValueCalc property (see Section 17 Calculated Value Properties).

When unparsing, an element declaration and the Infoset are considered as follows. An implementation MAY use any technique consistent with this algorithm:

a) If the element declaration has a dfdl:outputValueCalc property, then the expression which is the dfdl:outputValueCalc property value is evaluated, and the resulting value becomes the value of the element item in the augmented Infoset. Any pre-existing value for the Infoset item is superseded by this new value. References to other augmented Infoset items from within the dfdl:outputValueCalc expression MUST obtain their values from the augmented Infoset directly (when the value is already present) or by recursively using these methods (a) and (b) as needed.

b) If the element declaration has no corresponding value in the augmented Infoset, and the element declaration is for a required occurrence, and it has a default value specified, then an element item having the default value is created in the augmented Infoset.

c) If any Infoset item's value is requested recursively as a part of (a) above and (a) does not apply, and the corresponding value is not present, and (b) does not apply then it is a Processing Error.

Given this augmented Infoset, then if the element declaration has a corresponding Infoset item then that item is converted to its representation according to its DFDL properties. If the element declaration is for a required occurrence, and there is no value in the augmented Infoset then it is a Processing Error.
10 Overview: Representation Properties and their Format Semantics

The next sections specify the set of DFDL v1.0 properties that may be used in DFDL annotations in DFDL Schemas to describe data formats.

It is a Schema Definition Error when a DFDL schema does not contain a definition for a representation property that is needed to interpret the data. For example, a DFDL schema containing any textual data must provide a definition of the character set encoding property (dfdl:encoding) for that textual data, and if it is not part of the format properties context for that data, then it is a Schema Definition Error.

Furthermore, no default values are provided for representation properties as built-in definitions by any DFDL processor. This requires DFDL schemas to be explicit about the representation properties of the data they describe and avoids any possibility of DFDL schemas that are meaningful for some DFDL processors but not others.

The properties are organized as follows:

- Common to both Content and Framing (see 11)
- Common Framing, Position, and Length (see 12)
- Simple Type Content (see 13)
- Sequence Groups (see 14)
- Choice Groups (see 15)
- Array elements and optional elements (see 16)
- Calculated Values (see 17)

Where properties are specific to a physical representation, the property name may choose to reflect this. Where properties are related to a specific logical type grouping (defined below), the property name may choose to reflect this.

A limited number of properties can take a DFDL expression which must return a value of the proper type for the property. Those properties that take an expression explicitly state in the description. Other properties do not take an expression.

The property description defines which schema component that the property may be specified on. In addition, most DFDL properties may be specified on a dfdl:format annotation.
### 11 Properties Common to both Content and Framing

<table>
<thead>
<tr>
<th>Property Name</th>
<th>Description</th>
</tr>
</thead>
</table>
| byteOrder     | Enum or DFDL Expression  
|               | Valid values 'bigEndian', 'littleEndian'.  
|               | This property can be computed by way of an expression which returns the string 'bigEndian' or 'littleEndian'. The expression must not contain forward references to elements which have not yet been processed.  
|               | Note that there is, intentionally, no such thing as 'native' endian.  
|               | This property applies to all Number, Calendar (date and time), and Boolean types with representation binary. Specifically, that is binary integers, binary booleans, all packed decimals, binary floats, binary seconds and binary milliseconds.  
|               | This property is never used to establish the byte order for text /strings, as each character set encoding involving multiple bytes of data per code unit specifies its byte order.  
|               | Annotation: dfdl:element, dfdl:simpleType |

| bitOrder      | Enum  
|---------------|------|
|               | Valid values 'mostSignificantBitFirst', 'leastSignificantBitFirst'.  
|               | The bits of a byte each have a place value or significance of $2^n$, for $n$ from 0 to 7. Hence, the byte value $255 = 2^7 + 2^6 + 2^5 + 2^4 + 2^3 + 2^2 + 2^1 + 2^0$. A bit can always be unambiguously identified as the $2^n$-bit.  
|               | The bit order is the correspondence of a bit's numeric significance to the bit position (1 to 8) within the byte.  
|               | Value 'mostSignificantBitFirst' means:  
|               | • The $2^7$ bit is first, i.e., has bit position 1.  
|               | • In general, the $2^n$ bit has position $8 - n$.  
|               | • The least significant bits of byte $N$ are considered to be adjacent to the most significant bits of byte $N+1$.  
|               | Value 'leastSignificantBitFirst' means:  
|               | • The $2^0$ bit is first, i.e., has bit position 1.  
|               | • In general, the $2^n$ bit has position $n + 1$.  
|               | • The most significant bits of byte $N$ are considered to be adjacent to the least significant bits of byte $N+1$.  
|               | This property applies to all content and framing since it determines which bits of a byte occupy what bit positions. Content and framing are defined in terms of regions of the data stream, and these regions are defined in terms of the starting bit position and ending bit position; hence, dfdl:bitOrder is relevant to determining the specific bits of any grammar region (see Section 9.2 DFDL Data Syntax Grammar) when the region's starting bit position or ending bit position are not on a byte boundary.  

---

30 The concept of native-endian is avoided in DFDL since a DFDL schema containing such a property binding would not contain a complete description of data, but rather an incomplete one which would behave differently based on characteristics of the machine and implementation where the DFDL processor is executed. In DFDL this same behavior is achieved through the use of explicit parameterization using DFDL variables to set dfdl:byteOrder. See Section 7.7.1.2 Predefined Variables.
The bit order can only change on byte boundaries, and alignment of up to 7 bits is skipped (parsing) or inserted (unparsing) to ensure byte-alignment whenever the bit order changes.

**Annotation:** `dfdl:element`, `dfdl:simpleType`, `dfdl:sequence`, `dfdl:choice`, `dfdl:group`

<table>
<thead>
<tr>
<th>encoding</th>
<th>Enum or DFDL Expression</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Values are one of:</td>
</tr>
<tr>
<td></td>
<td>• IANA charset name(^{31})</td>
</tr>
<tr>
<td></td>
<td>• CCSID(^{32})</td>
</tr>
<tr>
<td></td>
<td>• DFDL standard encoding name</td>
</tr>
<tr>
<td></td>
<td>• Implementation-specific encoding name</td>
</tr>
</tbody>
</table>

This property can be computed by way of an expression which returns an appropriate string value. The expression must not contain forward references to elements which have not yet been processed.

Note that there is, deliberately, no concept of 'native' encoding\(^{33}\).

Conforming DFDL v1.0 processors MUST accept at least 'UTF-8', 'UTF-16', 'UTF-16BE', 'UTF-16LE', 'ASCII', and 'ISO-8859-1' as encoding names.

The encoding name "UTF-16" is equivalent to "UTF-16BE" and for processors that implement UTF-32, the encoding name "UTF-32" is equivalent to "UTF-32BE".

Unlike most other properties with Enum values, encoding names are case-insensitive, so for example 'utf-8', 'Utf-8', and 'UTF-8' are equivalent.

The encoding name 'UTF-8' is interpreted strictly and does not include variants such as CESU-8.

DFDL standard encoding names are defined in Section 33 Appendix D: DFDL Standard Encodings. When supported, a conforming DFDL implementation MUST implement them in a uniform manner so that they are portable across all DFDL implementations that implement them.

Additional implementation-defined encoding names MAY be provided only for character set encodings for which there is no IANA name standard nor CCSID standard nor DFDL standard encoding. These implementation-defined encodings MUST have "X-" as a prefix to their name, as they are subject to being superseded by IANA or DFDL standard encoding names.

**Annotation:** `dfdl:element`, `dfdl:simpleType`, `dfdl:sequence`, `dfdl:choice`, `dfdl:group`

<table>
<thead>
<tr>
<th>utf16Width</th>
<th>Enum</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Valid values are 'fixed', 'variable'.</td>
</tr>
</tbody>
</table>

---

\(^{31}\) IANA is the Internet Assigned Names Authority. See [IANA]  
\(^{32}\) CCSID stands for Coded Character Set ID, a decimal number syntax for a coded character set specifier. See [CCSID]  
\(^{33}\) The concept of native character encoding is avoided in DFDL since a DFDL schema containing such a property binding would not contain a complete description of data, but rather an incomplete one which would behave differently based on characteristics of the operating environment where the DFDL processor executes. In DFDL this same behavior is achieved through the use of explicit parameterization using DFDL variables to set `dfdl:encoding`. See Section 7.7.1.2 Predefined Variables.
Applies only when encoding is 'UTF-16', 'UTF-16BE', UTF16-LE' or their CCSID equivalents.

Specifies whether the encoding 'UTF-16' is treated as a fixed or variable width encoding. 'UTF-16' can contain characters which require two codepoints (called a surrogate pair) to represent. When utf16Width is 'fixed', these surrogate code points are treated as separate characters. When utf16Width is 'variable', then surrogate pairs are converted into a single character on parsing, and such a character is split into two characters on unparsing.

When utf16Width is 'variable', then on parsing an un-paired surrogate codepoint causes a decode error, which can be controlled via dfdl:encodingErrorPolicy described below.

Annotation: dfdl:element, dfdl:simpleType, dfdl:sequence, dfdl:choice, dfdl:group

### ignoreCase

**Enum**

Valid values are 'yes', 'no'.

Whether mixed case data is accepted when matching delimiters and data values on input.

Property ignoreCase plays no part when comparing an element value with an XSD enum facet, matching an element value to an XSD pattern facet, or comparing an element value with the XSD fixed property. It is therefore not used by validation (when validation is enabled), nor by the dfdl:checkConstraints function.

On unparsing always use the delimiters or value as specified.

Annotation: dfdl:element, dfdl:simpleType, dfdl:sequence, dfdl:choice, dfdl:group

### encodingErrorPolicy

**Enum**

Valid values are 'error' or 'replace'.

This property applies whenever dfdl:encoding is applicable.

This property provides control of how decoding and encoding errors are handled when converting the data to text, or text to data. This includes converting when scanning for delimiters, matching regular expression length or test patterns, matching textual data type representation patterns against the data, and of course isolating the text content that becomes the value of an element (parsing) or constructing the content from the value (unparsing).

When parsing, an error can occur when decoding characters from their encoded form into the DFDL Infoset character set (ISO10646). This can occur due to invalid byte sequences, or not enough bytes found to make up the full encoding of a character.

If 'replace', then the Unicode replacement character (U+FFFD) is substituted for the offending errors, one replacement character for any incorrect fragment of an encoding.

If 'error' then a Processing Error occurs.
When unparsing, the errors that can occur when encoding characters from Unicode/ISO 10646 into the specified encoding include when no mapping is provided by the encoding character set specification and when there is not enough space to output the entire encoding of the character (e.g., need 2 bytes for a 2-byte character codepoint, but only 1 byte remains in the available length.)

If 'replace' then encoding-specific replacement/substitution character is output. It is a Processing Error if no such character is defined, and it is a Processing Error if there is any error when attempting to output the replacement (such as not enough room for the representation of the entire encoding of the replacement character).

If 'error' then a Processing Error occurs.

See Section 11.2 Character Encoding and Decoding Errors for further details.

Annotation: dfdl:element, dfdl:simpleType, dfdl:sequence, dfdl:choice, dfdl:group

<table>
<thead>
<tr>
<th>dfdl:encodingErrorPolicy</th>
</tr>
</thead>
</table>

### Table 13 Properties Common to both Content and Framing

#### 11.1 Unicode Byte Order Mark (BOM)

DFDL does not provide any special treatment of Unicode Byte-Order Marks. They are treated as a Unicode ZWNBS character.

#### 11.2 Character Encoding and Decoding Errors

When parsing, these are the errors that can occur when decoding characters into Unicode/ISO 10646.

1. The data is broken - invalid bit/byte sequences are found which do not match the definition of a character for the encoding.
2. Not enough data is found to make up the entire encoding of a character. That is, a fragment of a valid encoding is found.

When unparsing, these are the errors that can occur when encoding characters from Unicode/ISO 10646 into the specified encoding.

1. No mapping provided by the encoding specification.
2. Not enough room to output the entire encoding of the character (e.g., need 3 bytes for a character encoding that uses 3-bytes for that character, but only 1 byte remains in the available length.

The subsections below describe how these errors are handled.

#### 11.2.1 Property dfdl:encodingErrorPolicy

The property dfdl:encodingErrorPolicy has two possible values: 'error' and 'replace'.

#### 11.2.1.1 dfdl:encodingErrorPolicy 'error'

If 'error', then any error when decoding characters while parsing causes a Processing Error. For unparsing, any error when encoding characters causes a Processing Error.

When parsing, it does not matter if this happens when scanning for delimiters, matching a regular expression, matching a literal nil value, or constructing the value of a textual element.

There is one exception. When dfdl:lengthUnits is 'bytes', the 'not enough data' decoding error is ignored, and the data making up the fragment character is skipped over. Symmetrically, when unparsing the 'not enough room' encoding error is ignored and the left-over bytes are filled with the dfdl:fillByte.

Detection of character set decoding errors is often implementation-dependent because DFDL Implementations are free to optimize processing speed by skipping character decoding or encoding whenever possible. For example: when character set encodings are fixed-width, it is...
possible to determine lengths in bytes or bits from the length in characters by multiplying the
length value by the character width, without having to decode any characters.

When parsing, character decoding errors MUST be detected when
   a) the decoding results in a character being placed into the DFDL Infoset
   b) the decoding is necessary to identify a delimiter
   c) the decoding is necessary to determine a match or non-match of a regular expression in
      a dfdl:assert or dfdl:discriminator with testKind='pattern'.

When unparsing, character encoding errors MUST be detected when
   d) an unmapped character appears in the Infoset value of an element.

In all other cases, character set decoding and encoding errors MAY not be detected.

Implementations MAY pre-decode a limited number of characters for efficiency; however, such
implementation-dependent pre-decoding can cause parse errors to be detected in some
implementations of DFDL that are not detected by others.

Schema authors are advised not to rely on decoding errors for backtracking to control the
behavior of the parser.

11.2.1.2 dfdl:encodingErrorPolicy 'replace' for parsing

If 'replace' then any error when decoding characters results in the insertion of the Unicode
Replacement Character (U+FFFD) as the replacement for that error.

It does not matter if this error and replacement happens when scanning for delimiters, matching a
regular expression, matching a literal nil value, or constructing the value of a textual element.

There is one exception. When dfdl:lengthUnits is 'bytes', the 'not enough data' decoding error is
ignored, no replacement character is created. The data making up the fragment character is
skipped over. (It is filled with the dfdl:fillByte when unparsing.)

Note that the "." wildcard in regular expressions matches the Unicode Replacement Character, so
"."* and \.+ regular expressions can potentially cause very large matches (up to the entire data
stream) to occur when data contains errors and dfdl:encodingErrorPolicy 'replace'. DFDL Schema
authors are advised that bounded length negated regular expressions can help in this case. E.g.,
[^\uFFFD]\[0,50]" says to match any character (excluding the Unicode Replacement Character),
but only up to length 50.

It is also worth noting that the Unicode Replacement Character can appear in data as an ordinary
character, and this cannot be distinguished from the insertion of the Unicode Replacement
Character due to a decoding error. This is likely to happen for data that is (a) initially parsed by a
DFDL parser with dfdl:encodingErrorPolicy 'replace', and (b) which contains some decoding
errors, but (c) is nevertheless successfully parsed, (d) is written back out to a file or other data
repository, and (e) is parsed again. The written data has replaced data errors with the Unicode
Replacement Character, and so if the data is parsed again, it no longer produces errors, but
instead contains the Unicode Replacement Character as a regular character in the data.

If dfdl:lengthUnits is 'characters', then a Unicode Replacement Character counts as contributing a
single character to the length.

If the data contains more than one adjacent decode error, then the specific number of Unicode
Replacement Characters that are inserted as the replacement of these errors is implementation-
dependent. That is, some implementations MAY view, for example, three consecutive erroneous
bytes as three separate decode errors, others MAY view them as a single or two decode errors.
All implementations MUST, however, insert some number of Unicode Replacement Characters,
and then continue to decode characters following the erroneous data.

The trimming of pad characters always happens after Unicode Replacement Characters have
been inserted into the data.

dfdl-wg@ogf.org
11.2.1.3 dfdl:encodingErrorPolicy 'replace' for unparsing

For unparsing, each encoding has a replacement/substitution character specified by the ICU. This character is substituted for the unmapped character or the character that has too large an encoding to fit in the available space.

There is one exception. When dfdl:lengthUnits is 'bytes', the 'not enough room' encoding error is ignored. The left-over bytes are filled with the dfdl:fillByte (they are skipped when parsing.)

The definitions of these substitution characters can be conveniently found for many encodings in the ICU Converter Explorer (http://demo.icu-project.org/icu-bin/convexp).

An encoding error is a Processing Error if the encoding does not provide a substitution/replacement character definition. (This would be rare but can occur if a DFDL implementation allows many encodings beyond the minimum set.)

11.2.2 Unicode UTF-16 Decoding/Encoding Non-Errors

The following specific situations involving encodings UTF-16, UTF-16LE, and UTF-16BE when dfdl:utf16Width "fixed", and they do not cause a decoding or encoding error.

- unpaired surrogate codepoint
- out-of-order surrogate codepoint pair
- surrogate codepoint pair is encountered

In all these cases the code-point(s) becomes a character code in the DFDL Information Item for the string.

11.2.3 Preserving Data Containing Decoding Errors

There can be situations where data wants to be preserved exactly even if it contains errors.

It is suggested that if a DFDL schema author wants to preserve information containing data where the encodings have these kinds of errors, that they model such data as xs:hexBinary, or as xs:string but using an encoding such as iso-8859-1 which preserves all bytes.

11.3 Byte Order and Bit Order

Byte order and bit order are separate concepts. However, of the possible combinations, only the following are allowed:

1. 'bigEndian' with 'mostSignificantBitFirst'
2. 'littleEndian' with 'mostSignificantBitFirst'
3. 'littleEndian' with 'leastSignificantBitFirst' 34

Other combinations MUST produce Schema Definition Errors.

11.4 dfdl:bitOrder Example

Consider a structure of 4 logical elements. The total length is 16 bits.

Assume the lengths here are measured in bits (dfdl:lengthUnits is 'bits'), and that these are binary integers (dfdl:representation is 'binary', dfdl:binaryNumberRep is 'binary'):

```
<element name="A" type="xs:int" dfdl:length="3"/> <!-- having value 3 -->
<element name="B" type="xs:int" dfdl:length="7"/> <!-- having value 9 -->
<element name="C" type="xs:int" dfdl:length="4"/> <!-- having value 5 -->
<element name="D" type="xs:int" dfdl:length="2"/> <!-- having value 1 -->
```

The above are colorized to highlight the corresponding bits in the data below.

In a format where dfdl:bitOrder is 'mostSignificantBitFirst':

```
01100010 01010101
AAAAAABB BBCCCCDD
```

34 Used by data format MIL-STD-2045
35 For dfdl:lengthUnits, see Section 12.3 Properties for Specifying Lengths.
36 For dfdl:binaryNumberRep, see Section 13.7 Properties Specific to Number with Binary Representation.
As presented here, the bits corresponding to each element appear left to right, and all bits for an individual element are adjacent. Within the bits of an individual element the most significant bit is on the left, least significant on the right, consistent with the way the bytes themselves are presented.

In contrast, in a format where dfdl:bitOrder is 'leastSignificantBitFirst':

```
01001011 01010100
BBBBBAAA DDCCCCBB
```

In the above presentation note how the bits of the element 'B' do not appear adjacent to each other. The most significant bits of byte N are adjacent to the least significant bits of byte N+1.

11.4.1 Example Using Right-to-Left Display for 'leastSignificantBitFirst'

When working exclusively with data having dfdl:bitOrder 'leastSignificantBitFirst', it is useful to present data with bytes Right to Left. That is, with the bytes starting at byte 1 on the right and increasing to the left.

```
01010101 01001011
DDCCBBB BBBBAAA
```

With this reorientation, the bits of the element 'B' are once again displayed adjacently. Within the bits of an individual element the most significant bit is on the left, least significant on the right, consistent with the way the bytes themselves are presented.

Often the specification documents for data formats using least-significant-bit-first bit order describe data using this Right-to-Left presentation style.

11.4.2 dfdl:bitOrder and Grammar Regions

When any grammar region appears before (to the left of) or after (to the right of) another grammar region in the grammar rules of Section 9.2, and the boundary between the two falls within a byte rather than on a byte boundary, then the dfdl:bitOrder determines which bits are occupied by the regions.

In general, the notion of before means occupying lower-numbered bit positions, and the bit positions are numbered according to dfdl:bitOrder. Hence, when dfdl:bitOrder is 'mostSignificantBitFirst', grammar regions that are before, occupy more-significant bits, and when dfdl:bitOrder is 'leastSignificantBitFirst', grammar regions that are before occupy less-significant bits.
12 Framing
Several properties are common across the various framing styles or are used to distinguish them. Generally, these have to do with position and length for text, bit fields, or opaque data.

12.1 Aligned Data
Alignment properties control the leading alignment and trailing alignment regions. That is, the LeadingAlignment and TrailingAlignment regions of the data syntax grammar (in Section 9.2).
When the alignment properties are applied to an array element, the properties are applied to each occurrence of the element; that is, not only to the first occurrence.
The following properties are used to define alignment rules.

<table>
<thead>
<tr>
<th>Property Name</th>
<th>Description</th>
</tr>
</thead>
</table>
| alignment     | Non-negative Integer or 'implicit'
|               | A non-negative number that gives the alignment required for the beginning of
|               | the item. If alignment is needed then the size of the AlignmentFill grammar
|               | region is non-zero if the item must be aligned to a boundary.
|               | 'implicit' specifies that the natural alignment for the representation type is
|               | used. See the table of implicit alignments Table 15 Implicit Alignment in bits
|               | for simple elements. The 'implicit' alignment of a complex element is the
|               | alignment of its model group. The 'implicit' alignment of a model group is
|               | always 1. If alignment is 'implicit' then dfdl:alignmentUnits is ignored.
|               | For textual data, minimum alignment is mandated by the character-set
|               | encoding, and this property must be 'implicit' or set to a multiple of the
|               | character-set's mandatory alignment. See Section 12.1.2.
|               | Annotation: dfdl:element, dfdl:simpleType, dfdl:sequence, dfdl:choice, dfdl:group |
| alignmentUnits| Enum
|               | Valid values are 'bits' or 'bytes'
|               | Scales the alignment so alignment can be specified in either units of bits or
|               | units of bytes.
|               | Only used when dfdl:alignment not 'implicit'
|               | Annotation: dfdl:element, dfdl:simpleType, dfdl:sequence, dfdl:choice, dfdl:group |
| fillByte       | DFDL String Literal
|               | A single byte specified as a DFDL byte value entity or a single character. If a
|               | character is specified, it must be a single-byte character in the applicable
|               | encoding.
|               | Used on unparsing to fill empty space such as between two aligned
|               | elements.
|               | Used to fill these regions specified in the grammar: RightFill,
|               | ElementUnused, ChoiceUnused, LeadingSkip, AlignmentFill, and
|               | TrailingSkip.
|               | Annotation: dfdl:element, dfdl:simpleType, dfdl:sequence, dfdl:choice, dfdl:group |
| leadingSkip   | Non-negative Integer
|               | A non-negative number of bytes or bits, depending on dfdl:alignmentUnits, to
|               | skip before alignment is applied. Gives the size of the grammar region having
|               | the same name.
Annotation: dfdl:element, dfdl:simpleType, dfdl:sequence, dfdl:choice, dfdl:group

trailingSkip

Non-negative Integer
A non-negative number of bytes or bits, depending on dfdl:alignmentUnits, to skip after the element, but before considering the alignment of the next element. Gives the size of the grammar region having the same name. If dfdl:trailingSkip is specified when dfdl:lengthKind is 'delimited' then a dfdl:terminator must be specified.
Annotation: dfdl:element, dfdl:simpleType, dfdl:sequence, dfdl:choice, dfdl:group

Table 14 Aligned Data Properties
There are two properties which control the data alignment by controlling the length of the AlignmentFill region

- alignment - an integer 1 or greater
- alignmentUnits - bits or bytes

An element's representation is aligned to N units if P is the first position in the representation and P mod N = 1. When parsing, the position of the first unit of the data stream is 1.

For example, if dfdl:alignment is 4, and dfdl:alignmentUnits is 'bytes', then the element's representation must begin at 1 or 1 plus a multiple of 4 bytes. That is, 1, 5, 9, 13, 17 and so on.

The length of the AlignmentFill region is measured in bits. If alignmentUnits is 'bytes' then the processor multiplies the alignment value by 8 to get the bit alignment. If the position in the data stream of the start of the AlignmentFill region is bit position N, then the length of the AlignmentFill region is the smallest non-negative integer L such that (L + N) mod B = 1. The position of the first bit of the aligned component is P = L + N.

The LeadingSkip and TrailingSkip regions length are controlled by two properties of corresponding names and the dfdl:alignmentUnits property.

12.1.1 Implicit Alignment

When dfdl:alignment is 'implicit' the following alignment values are applied for each logical type.

<table>
<thead>
<tr>
<th>Type</th>
<th>Alignment</th>
</tr>
</thead>
<tbody>
<tr>
<td>text</td>
<td>binary</td>
</tr>
</tbody>
</table>
### Table 15 Implicit Alignment in bits

<table>
<thead>
<tr>
<th>Type</th>
<th>Encoding Specific</th>
<th>Not applicable</th>
</tr>
</thead>
<tbody>
<tr>
<td>String</td>
<td>Encoding Specific (usually 8 bits, with exceptions: See Section 12.1.2)</td>
<td>Not applicable</td>
</tr>
<tr>
<td>Float</td>
<td>32</td>
<td></td>
</tr>
<tr>
<td>Double</td>
<td>64</td>
<td></td>
</tr>
<tr>
<td>Decimal, Integer, nonNegativeInteger</td>
<td>Packed decimals: 8</td>
<td>binary: 8</td>
</tr>
<tr>
<td>Long, UnsignedLong</td>
<td>binary: 64</td>
<td></td>
</tr>
<tr>
<td>Int, UnsignedInt</td>
<td>binary: 32</td>
<td></td>
</tr>
<tr>
<td>Short, UnsignedShort</td>
<td>binary: 16</td>
<td></td>
</tr>
<tr>
<td>Byte, UnsignedByte</td>
<td>binary: 8</td>
<td></td>
</tr>
<tr>
<td>DateTime</td>
<td>binarySeconds: 32, binaryMilliseconds: 64</td>
<td></td>
</tr>
<tr>
<td>Date</td>
<td>binarySeconds: 32, binaryMilliseconds: 64</td>
<td></td>
</tr>
<tr>
<td>Time</td>
<td>binarySeconds: 32, binaryMilliseconds: 64</td>
<td></td>
</tr>
<tr>
<td>Boolean</td>
<td>32</td>
<td></td>
</tr>
<tr>
<td>HexBinary</td>
<td>Not applicable</td>
<td></td>
</tr>
<tr>
<td></td>
<td>8</td>
<td></td>
</tr>
</tbody>
</table>

Note: The above table specifies the implicit alignment in bits, but this does not imply that `dfdl:alignmentUnits 'bits'` can be specified for all simple types. Rather, `dfdl:alignmentUnits` and `dfdl:lengthUnits` are independent and have their own rules for when they are applicable.

#### 12.1.2 Mandatory Alignment for Textual Data

**Textual Data** – This term is used to describe data of type `xs:string`, data with `dfdl:representation "text"`, as well as data being matched to delimiters (parsing) or output as delimiters (unparsing), and data being matched to regular expressions (parsing only - as in a `dfdl:assert` with `testKind 'pattern'`, or an element with `dfdl:lengthKind 'pattern'`).

Textual data has mandatory alignment that is character-set-encoding dependent. That is, these mandates come from the character set encoding specified by the `dfdl:encoding` property.

When processing textual data, it is a Schema Definition Error if the `dfdl:alignment` and `dfdl:alignmentUnits` properties are used to specify alignment that is not a multiple of the encoding-specified mandatory alignment.

If the data is not aligned to the proper boundary for the encoding when textual data is processed, then bits are skipped (parsing) or filled from `dfdl:fillByte` (unparsing) to achieve the mandatory alignment.

All required character set encodings in DFDL have 8-bit/1-byte alignment.

DFDL standard encodings specify their alignment. See Section 33 Appendix D: DFDL Standard Encodings.

Some implementations MAY include additional implementation-defined encodings which have other alignments.

Note the 16-bit and 32-bit Unicode character set encodings UTF-16, UTF-16BE, UTF-16LE, UTF-32, UTF-32BE, UTF-32LE, all have 8-bit/1-byte alignment.
12.1.3 Mandatory Alignment for Packed Decimal Data

Packed decimal data is data with dfdl:binaryNumberRep values of 'packed', 'ibm4690Packed' or 'bcd'. This representation stores a decimal digit in a 4 bit nibble. These nibbles must have a multiple of 4-bit alignment. It is a Schema Definition Error otherwise.

12.1.4 Example: AlignmentFill

When dfdl:alignmentUnits is 'bits', and the dfdl:alignment is not a multiple of 8, then the dfdl:bitOrder property affects the alignment by controlling which bits are skipped as part of the grammar AlignmentFill region.

In general, the AlignmentFill region is before the regions it is aligning, and within a byte, the meaning of 'before' is interpreted with respect to the dfdl:bitOrder.

When dfdl:bitOrder is 'mostSignificantBitFirst', then bits with more significance are before bits with less significance, so the AlignmentFill region occupies the most significant bits of the byte.

When dfdl:bitOrder is 'leastSignificantBitFirst', then bits with less significance are before bits with more significance, so the AlignmentFill region occupies the least significant bits of the byte.

Consider a structure of 2 logical elements. Assume the length and alignment units are bits. (dfdl:lengthUnits='bits', dfdl:alignmentUnits='bits'), and that the data is binary with two's-complement binary integers (dfdl:representation='binary', dfdl:binaryNumberRep='binary'), and assume the data is at the beginning of the data stream.

```
<element name="A" type="xs:int" dfdl:length="2" dfdl:alignment='8'/>
<!-- having value 1 -->
<element name="B" type="xs:int" dfdl:length="4" dfdl:alignment='4'/>
<!-- having value 5 -->
```

The above are colorized to highlight the corresponding bits in the data below. The total length due to the alignment region appearing before element 'B' is 8 bits.

In a format where dfdl:bitOrder is 'mostSignificantBitFirst' the data can be visualized as:

```
01000101
AAxxBBBB
```

<table>
<thead>
<tr>
<th>Significance</th>
<th>M</th>
<th>L</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bit Position</td>
<td>12345678</td>
<td></td>
</tr>
</tbody>
</table>

In the above, the AlignmentFill region is marked with 'x' characters and contains all 0 bit values.

In a format where dfdl:bitOrder is 'leastSignificantBitFirst' the presentation is different:

```
01010001
BBBBxxAA
```

<table>
<thead>
<tr>
<th>Significance</th>
<th>M</th>
<th>L</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bit Position</td>
<td>87654321</td>
<td></td>
</tr>
</tbody>
</table>

In the above the AlignmentFill region still appears before element 'B', and in this case that is in less significant bits of the byte than the bits of content of element 'B', and these bits are displayed to the right of the bits of element 'B'.

12.2 Properties for Specifying Delimiters

The following properties apply to all objects that use text delimiters to delimit, that is, to initiate and/or terminate data. Delimiters can apply to binary data; however, they are most often called 'text' delimiters because the concept is much more commonly used for textual data formats.

When parsing, there can be multiple delimiter candidates to be matched against the data stream. The matching is performed in a longest-match preferred manner. That is, each of the delimiter candidates is matched against the data, taking the longest match possible for that candidate. Then across all the delimiter candidates, the one with the longest match is the one that is selected as having been found. Once a matching delimiter is found, no other matches are subsequently attempted (i.e., there is no backtracking to try shorter matches.) Additional details

---

For dfdl:binaryNumberRep, see Section 13.7 Properties Specific to Number with Binary Representation.
on the matching of DFDL String Literals are given in Appendix C: Processing of DFDL String literals.

<table>
<thead>
<tr>
<th>Property Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>initiator</td>
<td>List of DFDL String Literals or DFDL Expression</td>
</tr>
</tbody>
</table>

Specifies an ordered whitespace separated list of alternative DFDL String Literals one of which marks the beginning of the element or group of elements.

This property can be computed by way of an expression which returns a string containing a whitespace separated list of DFDL String Literals. The expression must not contain forward references to elements which have not yet been processed. It is not permitted for an expression to return an empty string or a string containing only whitespace. That is a Schema Definition Error.

Each string literal in the list, whether apparent in the schema, or returned as the value of an expression, is restricted to allow only certain kinds of DFDL String Literal syntax:

- DFDL character entities are allowed.
- DFDL Byte Value entities ( %#rXX; ) are allowed.
- DFDL Character Classes NL, WSP, WSP+, WSP*, and ES are allowed.
- If the ES entity or the WSP* entity appear alone as one of the string literals in the list, then dfdl:initiatedContent must be "no". This restriction ensures that when dfdl:initiatedContent is 'yes' that the initiator cannot match zero-length data.

If the above rules are not followed it is a Schema Definition Error.

The **Initiator** region contains one of the initiator strings defined by dfdl:initiator.

When parsing, once a matching initiator is found, no other matches are subsequently attempted (i.e., there is no backtracking).

When an initiator is specified, it is a Processing Error if the component is required and one of the values is not found.

If dfdl:initiator is "" (the empty string), that is the way a DFDL schema expresses a format which does not use initiators. Hence, the **Initiator** region is of length zero.

On unparsing the first initiator in the list is automatically inserted into the **Initiator** region.

If dfdl:ignoreCase is 'yes' then the case of the string is ignored by the parser.

Annotation: dfdl:element, dfdl:simpleType, dfdl:sequence, dfdl:choice, dfdl:group
### terminator

<table>
<thead>
<tr>
<th>List of DFDL String Literals or DFDL Expression</th>
</tr>
</thead>
<tbody>
<tr>
<td>Specifies an ordered whitespace separated list of alternative text strings that one of which marks the end of an element or group of elements. The strings MUST be searched for in the longest first order. This property can be computed by way of an expression which returns a string of whitespace separated list of values. The expression must not contain forward references to elements which have not yet been processed. This property can be used to determine the length of an element as described in Section 12.3.2 dfdl:lengthKind ’delimited’. Each string literal in the list, whether apparent in the schema, or returned as the value of an expression, is restricted to allow only certain kinds of DFDL String Literal syntax:</td>
</tr>
<tr>
<td>• DFDL character entities are allowed.</td>
</tr>
<tr>
<td>• DFDL Byte Value entities ( %#rXX; ) are allowed.</td>
</tr>
<tr>
<td>• DFDL Character Classes NL, WSP, WSP+, WSP*, and ES are allowed.</td>
</tr>
<tr>
<td>• Neither the ES entity nor the WSP* entity may appear on their own as one of the string literals in the list when the parser is determining the length of a component by scanning for delimiters. If the above rules are not followed it is a Schema Definition Error.</td>
</tr>
<tr>
<td>The Terminator grammar region contains one of the terminator strings defined by dfdl:terminator. If dfdl:terminator is &quot;&quot; (the empty string), that is the way a DFDL schema expresses a format which does not use terminators. Hence, the Terminator region is of length zero. It is not permitted for an expression to return an empty string, that is a Schema Definition Error. When parsing, once a matching terminator is found, no other matches are subsequently attempted (i.e., there is no backtracking). When a terminator is expected it is a Processing Error if no matching terminator is found. However, if dfdl:documentFinalTerminatorCanBeMissing is specified then it is not an error if the last terminator in the data stream is not found. On unparsing the first terminator in the list is automatically inserted in the Terminator region. If dfdl:ignoreCase is 'yes' then the case of the string is ignored by the parser. Annotation: dfdl:element, dfdl:simpleType, dfdl:sequence, dfdl:choice, dfdl:group</td>
</tr>
</tbody>
</table>
emptyValueDelimiterPolicy

Valid values are 'none', 'initiator', 'terminator' or 'both'

Indicates that when an element in the data stream is empty, which of initiator, terminator, both, or neither must be present.

Ignored if both dfdl:initiator and dfdl:terminator are "" (empty string).

'initiator' indicates that, on parsing, if the content region (which can be either the SimpleContent region or the ComplexContent region defined in Section 9.2) is empty then the dfdl:initiator must be present. It also indicates that on unparsing when the content region is empty that the dfdl:initiator is output.

'terminator' indicates that, on parsing, if the content region is empty then the dfdl:terminator must be present. It also indicates that on unparsing when the content region is empty the dfdl:terminator is output.

'both' indicates that, on parsing, if the content region is empty both the dfdl:initiator and dfdl:terminator must be present. On unparsing when the content region is empty the dfdl:initiator followed by the dfdl:terminator is output.

'none' indicates that if the content region is empty neither the dfdl:initiator or dfdl:terminator must be present. On unparsing when the content region is empty nothing is output.

It is a Schema Definition Error if dfdl:emptyValueDelimiterPolicy set to 'none' or 'terminator' when the parent group has dfdl:initiatedContent 'yes'.

This property plays an important role in establishing empty representation. See 9.2.2 Empty Representation for details.

This property is ignored if the element is fixed-length and length is not zero (as no empty representation is possible).

The value of dfdl:emptyValueDelimiterPolicy MUST only be checked if there is a dfdl:initiator or dfdl:terminator in scope. If so, and dfdl:emptyValueDelimiterPolicy is not set, it is a Schema Definition Error.

If dfdl:initiator is not "" and dfdl:terminator is "" and dfdl:emptyValueDelimiterPolicy is 'terminator' it is a Schema Definition Error.

If dfdl:terminator is not "" and dfdl:initiator is "" and dfdl:emptyValueDelimiterPolicy is 'initiator' it is a Schema Definition Error.

It is not a Schema Definition Error if dfdl:emptyValueDelimiterPolicy is 'both' and one or both of dfdl:initiator and dfdl:terminator is "". This is

</tr>
</tbody>
</table>
When 'treatAsEmpty' if an occurrence of an element has the empty representation when parsed, the behaviour is as stated in Section 9 for an occurrence with empty representation. Consequently, default values or empty strings may be added to the Infoset.

When 'treatAsAbsent' if an occurrence of an element has the empty representation when parsed, the behaviour is as stated in Section 9 for an absent occurrence. Consequently, default values or empty strings are never added to the Infoset.

Annotation: dfdl:element, dfdl:simpleType

Table 16 Properties for Specifying Delimiters

12.3 Properties for Specifying Lengths

These properties are used to determine the content length of an element and apply to elements of all types (simple and complex).

<table>
<thead>
<tr>
<th>Property Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>lengthKind</td>
<td>Enum</td>
</tr>
<tr>
<td></td>
<td>Controls how the content length of the component is determined. Valid values are: 'explicit', 'delimited', 'prefixed', 'implicit', 'pattern', 'endOfParent' A full description of each enumeration is given in the subsections of this section beginning with Section 12.3.1. 'explicit' means the length of the element is given by the dfdl:length property. 'delimited' means the element length is determined by scanning for a terminator or separator. 'prefixed' means the length of the element is given by an immediately preceding PrefixLength data region the format of which is specified using dfdl:prefixLengthType. 'implicit' means the length is to be determined in terms of the type of the element and its schema-specified properties if any. 'pattern' means the length of the element is given by scanning for a regular expression specified using the dfdl:lengthPattern property. 'endOfParent' means that the length extends to the end of the containing (parent) construct. Annotation: dfdl:element, dfdl:simpleType</td>
</tr>
<tr>
<td>lengthUnits</td>
<td>Enum</td>
</tr>
</tbody>
</table>
|               | Valid values 'bytes', 'characters', and 'bits'. Specifies the units to be used whenever a length is being used to extract or write data. Applicable when dfdl:lengthKind is 'explicit', 'implicit' (for xs:string and xs:hexBinary) or 'prefixed'. Usage is restricted as follows: 'characters' may only be used for complex elements and simple elements with text representation. 'bits' may only be used for xs:boolean, xs:byte, xs:short, xs:int, xs:long, xs:unsignedByte, xs:unsignedShort, xs:unsignedInt, and xs:unsignedLong simple types with binary representation, and for
calendar (date and time) simple types with binary packed representation.
• 'bytes' must be used for type xs:hexBinary and for types xs:float and xs:double with binary representation. 'bytes' may be used for any other type.
Annotation: dfdl:element, dfdl:simpleType

Table 17 Properties for Specifying Length

<table>
<thead>
<tr>

Annotation: dfdl:element, dfdl:simpleType</td>
</tr>
</tbody>
</table>

Table 18 The dfdl:length Property

When dfdl:lengthKind 'explicit', the method of extracting data is described in Section: 12.3.7 Elements of Specified Length

12.3.2 dfdl:lengthKind 'delimited'

On parsing, the length of an element with dfdl:lengthKind 'delimited' is determined by scanning the data stream for the delimiter.

The data stream is scanned for any of
• the element's terminator (if specified)
• an enclosing construct's separator or terminator
• the end of an enclosing element designated by its known length
• the end of the data stream

dfdl:lengthKind 'delimited' may be specified for
• elements of simple type with text representation
• elements of number or calendar (date and time) simple type with dfdl:representation 'binary' that have a packed decimal representation
• elements of type xs:hexBinary
• elements of complex type.

The rules for resolving ambiguity between delimiters are:
1. When two delimiters have a common prefix, the longest delimiter is tried first.
2. When two delimiters have the same length, but on different schema components, the innermost (most deeply nested) delimiter is tried first.

3. When the separator and terminator on a group have the same value, then at a point in the data where either the separator or terminator could be found, the separator is tried first. (Speculative execution may try the terminator subsequently).

4. If the length of the delimiters cannot be determined because character class entities of variable length are being used then the delimiters MUST each be matched against the data, and the longest matching delimiter is taken as the match for the delimiter.

5. Ties (same matched length) are broken by giving a separator priority over a terminator of a sequence, or by choosing the innermost, or first in schema order.

When unparsing a simple element with text representation, the length in the data stream is the length of the content region, padded to a minimum length if dfdl:textPadKind is 'padChar'. For xs:string elements this length is the XSD minLength facet value, for the other types it is dfdl:textOutputMinLength property value.

When unparsing a simple element with binary representation, then for hexBinary the length is the number of bytes in the Infoset value padded to the XSD minLength facet value using dfdl:fillByte, and for the other types the length is the minimum number of bytes to represent the value and any sign.

When unparsing a complex element, the length is that of the ComplexContent region.

12.3.2.1 Non-Delimited Elements within Delimited Constructs

When a simple or complex element has a specified length, dfdl:lengthKind 'pattern', or dfdl:lengthKind 'endOfParent' then delimiter scanning is suspended for the duration of the processing of that element.

This allows formats to be parsed which are delimited but have nested elements which contain non-character data so long as that nested data can be isolated from the delimited data context surrounding it.

12.3.2.2 Delimited Binary Data

Formats involving binary data, most notably packed decimals, can use delimiter scanning but care must be taken that the delimiters cannot match data represented in these formats. In particular, the delimiters must be chosen with knowledge that BCD data can contain any byte both of whose nibbles are 0 to 9 (that is, excluding A to F). Packed data adds bytes with a sign indicator, that is, a nibble in the range A to F.

General binary data can contain any bit pattern whatsoever, so delimiter scanning for numbers and calendar types with dfdl:representation 'binary' is disallowed, with the specific exception of packed decimals. Delimiter scanning is also allowed for type xs:hexBinary.

Implementation Note: Scanning for delimiters when data is binary, or when using byte-value (aka raw byte) entities in delimiters, means that a simple character-based delimiter scanner IS NOT sufficient, as the delimiter may not be representable as characters.

12.3.3 dfdl:lengthKind 'implicit'

When dfdl:lengthKind is 'implicit', the length is determined in terms of the type of the element and its schema-specified properties.

For complex elements, 'implicit' means the length is determined by the combined lengths of the contained children, that is the ComplexValue region, and the ElementUnused region is of size 0. However, note that alignment regions inside the contained children within the ComplexValue region may be of different lengths depending on the ComplexValue's starting position alignment.

For simple elements the length is fixed and is given in Table 19 Length in Bits for SimpleTypes when dfdl:lengthKind is 'implicit'.

<table>

<td>Not applicable</td>
</tr>
</tbody>
</table>

**Table 19 Length in Bits for SimpleTypes when dfdl:lengthKind is 'implicit'**

- 'Not Allowed' means that there is no implicit length for the combination of simple type and representation, and it is a Schema Definition Error if dfdl:lengthKind 'implicit' is specified.
- packed decimal means dfdl:binaryNumberRep is 'packed', 'bcd', or 'ibm4690Packed'
- binary means dfdl:binaryNumberRep is 'binary'
- binarySeconds means dfdl:binaryCalendarRep is 'binarySeconds'
- binaryMilliseconds means dfdl:binaryCalendarRep is 'binaryMilliseconds'.
When dfdl:lengthKind is 'implicit', the method of extracting data is described in Section 12.3.7 Elements of Specified Length.

It is a Schema Definition Error if type is xs:string and dfdl:lengthKind is 'implicit' and dfdl:lengthUnits is 'bytes' and encoding is not an SBCS (exactly 1 byte per character code) encoding. This prevents a scenario where validation against the XSD maxLength facet is in characters but parsing and unparsing using the XSD maxLength facet is in bytes.

12.3.4 dfdl:lengthKind 'prefixed'

When dfdl:lengthKind is 'prefixed' the length of the element is given by the integer value of the PrefixLength region specified using dfdl:prefixLengthType. The property dfdl:prefixIncludesPrefixLength also can be used to adjust the length appropriately.

When dfdl:lengthKind is 'prefixed' the method of extracting data is described in Section 12.3.7 Elements of Specified Length

When dfdl:lengthKind is 'prefixed', delimiter scanning is turned off and in-scope delimiters are not looked for within or between elements.

</tbody>
</table>

Table 20 Properties for dfdl:lengthKind 'prefixed'

The representation of the element is in two parts.

1. The 'prefix length' is an integer which specifies the length of the element's content. The representation of the length prefix is described by a simple type which is identified using the dfdl:prefixLengthType property.
2. The content of the element.

When parsing, the length of the element's content is obtained by parsing the simple type specified by dfdl:prefixLengthType to obtain an integer value. Note that all required properties
must be present on the specified simple type or defaulted because there is no element declaration to supply any missing required properties.

If the dfdl:prefixIncludesPrefixLength property is 'yes' then the length of the element's content is the value of the prefix length minus the length of the content of the prefix length.

If the prefix type is dfdl:lengthKind 'implicit' or 'explicit' then the dfdl:lengthUnits properties of both the prefix type and the element must be the same.

The DFDL properties that specify the format of the prefix come from annotations directly on the dfdl:prefixLengthType's type definition, and from the default format annotation for the schema document containing the definition of that type. If the using-element resides in a separate schema, the simple type does not pick up values from the element's schema's default dfdl:format annotation.

When unparsing, the length of the element's content region can be determined first as described below. Then the value of the prefix length MUST be adjusted based on the value of the dfdl:prefixIncludesPrefixLength property.

Then the prefix length can be written to the data stream using the properties on the dfdl:prefixLengthType, and finally the element's content can be written to the data stream.

Consider this example:

```xml
<xs:element name="myString" type="xs:string"
   dfdl:lengthKind="prefixed"
   dfdl:prefixIncludesPrefixLength="no"
   dfdl:prefixLengthType="packed3"/>
<xs:simpleType name="packed3"
   dfdl:representation="binary"
   dfdl:binaryNumberRep="packed"
   dfdl:lengthKind="explicit"
   dfdl:length="2" >
   <xs:restriction base="integer" />
</xs:simpleType>
```

In the above, the string has a prefix length of type 'packed3' containing 3 packed decimal digits.

The property dfdl:prefixIncludesPrefixLength is an enumeration which allows the length computation to be varied to include or exclude the length of the prefix element itself.

The prefix length's value contains the length measured in units given by dfdl:lengthUnits.

When parsing, if the dfdl:lengthUnits are bits, then any number of bits can be in the representation. However, the same is not true when unparsing. The DFDL Infoset does not store the number of bits in a number, so the number of bits is always be a multiple of 8 bits.

When unparsing, the value of the prefix is computed automatically by obtaining the length of the element's content.

For a simple element with text representation, the length is computed as for dfdl:lengthKind 'delimited'.

For a simple element with binary representation, the length is given in the table below.

For a complex element, the length is that of the ComplexContent region.

</tr>
</tbody>
</table>

12.3.4.1 **Nested Prefix Lengths**

It is possible for a prefix length, as specified by dfdl:prefixLengthType, to itself have a prefix length.

It is a Schema Definition Error if this nesting exceeds 1 deep. That is, an element can have a prefix length, which defines a PrefixLength region (see Section 9.2 DFDL Data Syntax Grammar). The PrefixLength region can itself have a type which also specifies a prefix length, thereby defining a PrefixPrefixLength region. It is a Schema Definition Error unless the type associated with the PrefixPrefixLength is different from the type associated with the PrefixLength.

12.3.5 **dfdl:lengthKind 'pattern'**

The dfdl:lengthKind 'pattern' means the length of the element is given by a regular expression specified using the dfdl:lengthPattern property. The DFDL processor scans the data stream to determine a string value that is the match to a regular expression. The pattern is only used on parsing.

When dfdl:lengthKind is 'pattern', delimiter scanning is turned off and in-scope delimiters are not looked for within or between elements.

<table>
<thead>
<tr>
<th>Property Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>lengthPattern</td>
<td>DFDL Regular Expression. Only used when lengthKind is 'pattern'. Specifies a regular expression that, on parsing, is executed against the data stream to determine the length of the element. The data stream beginning at the starting offset of the content region (which can be either the SimpleContent region or the ComplexContent region defined in Section 9.2 DFDL Data Syntax Grammar) of the element is interpreted as a stream of characters in the encoding of the element, and the regular expression contained in the dfdl:lengthPattern property is executed against</td>
</tr>
</tbody>
</table>

---

38This feature allows DFDL to describe the needed “one more level” of prefix that is needed for modeling an ASN.1 format, but without the complexities of general recursion.
that stream of characters. When the element is complex the encoding used is
the dfdl:encoding of the complex element itself.
It is a Schema Definition Error if there is no value for the dfdl:encoding
property in scope.
DFDL Escape Schemes (per dfdl:escapeSchemeRef) are not used when
executing the regular expression.
If the pattern matching of the regular expression reads data that cannot be
decoded into characters of the current encoding, then the behavior is
controlled by the dfdl:encodingErrorPolicy property. See
dfdl:encodingErrorPolicy in Section 11 Properties Common to both Content
and Framing.
Annotation: dfdl:element, dfdl:simpleType

Table 22 The dfdl:lengthPattern Property
On unparsing the behavior is the same as for dfdl:lengthKind 'prefixed'.
When the DFDL regular expression is matched against data:
- The data is considered to be text in the character set encoding specified by the
dfdl:encoding property, regardless of the actual representation of the element.
- The data is decoded from the specified encoding into Unicode before the actual matching
takes place.
- If there is no match (i.e., the length of the data found to match the pattern is zero) it is not
  a Processing Error but instead it means the length is zero.

12.3.6 dfdl:lengthKind 'endOfParent'
The dfdl:lengthKind 'endOfParent' means that the element is terminated either by the end of the
data stream, or the end of an enclosing complex element with dfdl:lengthKind 'explicit', 'pattern',
'prefixed' or 'endOfParent', or the end of an enclosing choice with dfdl:choiceLengthKind 'explicit'.
The 'parent' element or choice does not have to be the immediate enclosing component of the
element, but there must be no other components defined between the element specifying
dfdl:lengthKind 'endOfParent' and the end of the parent.
A convenient way of describing the parent is as a 'box', being defined as a portion of the data
stream that has an established content length prior to the parsing of its children. If the parent is
such a 'box' then the element specifying dfdl:lengthKind 'endOfParent' is the last element in the
'box' and its content extends to the end of the 'box'.
A dfdl:lengthKind of 'endOfParent' can only be used on simple and complex elements in the
following locations:
- When the immediate containing model group is a sequence, on the final element in the
  sequence
- When the immediate containing model group is a choice, on any element that is a branch
  of the choice
- A simple type or global element declaration referenced by one of the above.
- A global element declaration that is the document root.

It is a Schema Definition Error if:
- the element has a terminator.
- the element has dfdl:trailingSkip not equal to 0.
- the element has maxOccurs > 1.
- any other model-group is defined between this element and the end of the enclosing
  component.
- any other represented element is defined between this element and the end of the
  enclosing component.
- the parent is an element with dfdl:lengthKind 'implicit' or 'delimited'.

dfdl-wg@ogf.org
• the element has text representation, does not have a single-byte character set encoding, and the effective length units of the parent is not 'characters'.
• The effective length units of the parent are:
  o dfdl:lengthUnits if parent is an element with dfdl:lengthKind 'explicit' or 'prefixed';
  o 'characters' if parent is an element with dfdl:lengthKind 'pattern';
  o 'bytes' if parent is a choice with dfdl:choiceLengthKind 'explicit';
  o 'characters' if the element is the document root;
  o the effective length units of the parent's parent if parent is an element with dfdl:lengthKind 'endOfParent'

If the element is in a sequence then it is a Schema Definition Error if:
• the dfdl:separatorPosition of the sequence is 'postfix'
• the dfdl:sequenceKind of the sequence is not 'ordered'
• the sequence has a terminator
• there are floating elements in the sequence
• the sequence has a non-zero dfdl:trailingSkip

If the element is in a choice where dfdl:choiceLengthKind is 'implicit' then it is a Schema Definition Error if:
• the choice has a terminator
• the choice has a non-zero dfdl:trailingSkip

A simple element must have one of:
• type xs:string
• dfdl:representation 'text'
• type xs:hexBinary
• dfdl:representation 'binary' and a packed decimal representation

A complex element can have dfdl:lengthKind 'endOfParent'. If so then its last child element can be any dfdl:lengthKind including 'endOfParent'.

The dfdl:lengthKind 'endOfParent' can also be used on the document root to allow the last element to consume the data up to the end of the data stream.

The use of dfdl:lengthKind 'endOfParent' is distinct from the situation where the length of the last element in the parent is known but is not sufficient to fill the parent. In the latter case the remaining data are ignored on parsing and filled with dfdl:fillByte on unparsing.

When parsing an element with dfdl:lengthKind 'endOfParent', delimiter scanning is turned off and in-scope terminating delimiters are not looked for within the element.

When unparsing an element with dfdl:lengthKind 'endOfParent', if the parent is a complex element with dfdl:lengthKind 'explicit' where dfdl:length is not an expression, or a choice with dfdl:choiceLengthKind 'explicit', then the element with dfdl:lengthKind 'endOfParent' is padded or filled in the usual manner to the required length, by completing the LeftPadding, RightPad, RightFill, ElementUnused, or ChoiceUnused regions of the data syntax grammar (Section 9.2) as appropriate.

12.3.7 Elements of Specified Length

An element has a specified length when dfdl:lengthKind is 'explicit', 'implicit' (simple type only) or 'prefixed'. The units that the length represents are specified by the dfdl:lengthUnits property except where noted in Section 12.3.3.

Using specified length, it is possible for an element to have content length longer than needed to represent just the data value. For example, a simple text element may be padded in the RightPadding region if the data is not long enough.

When an element has specified length but appears inside a complex type element having delimited length kind, delimiter scanning is turned off and in-scope delimiters are not looked for within or between elements.

An element of specified length with dfdl:lengthKind 'implicit' or 'explicit' where dfdl:length is not an expression has a known length when unparsing.
An element of specified length with dfdl:lengthKind 'prefixed' is considered to have a *variable* length when unparsing. Specifically, the processor automatically determines the value to store in the prefix, based on the length of the SimpleContent or ComplexContent regions, and the properties which modify the interpretation of the prefix length value, such as dfdl:prefixIncludesPrefixLength.

For dfdl:lengthKind 'explicit' (expression), whether parsing or unparsing the expression is evaluated to obtain the length. When unparsing the processor cannot automatically determine in what way the length information is to be stored as it comes from an expression that may access one or more elements and perform any calculation. Hence, normally the value of the element or elements involved in the length calculation would be computed using dfdl:outputValueCalc, using an expression that measures the length of the element by way of functions such as dfdl:contentLength or dfdl:valueLength.

When parsing, if the data stream ends without enough data to parse an element, that is, N bits are needed based on the dfdl:length, but only M < N bits are available, then it is a Processing Error.

If dfdl:lengthUnits is 'characters' then the length (in bits) of the content region (i.e., SimpleContent or ComplexContent defined in Section 9.2 DFDL Data Syntax Grammar) depends on the encoding of the characters.

- If the dfdl:encoding property specifies a fixed-width encoding then the content length is the character width (in bits) multiplied by the length.
- If the dfdl:encoding property specifies a variable-width encoding then the length depends on the actual characters in the element's value. The characters MUST be decoded one by one, adding up their widths (in bits), while counting to the specified length value.

For a simple element, dfdl:lengthUnits 'characters' may only be used for textual elements, it is a Schema Definition Error otherwise.

Some DFDL implementations MAY support character set encodings where the characters are not a multiple of 8-bits wide. Encodings which are 5, 6, 7, and 9 bits wide are rare, but do exist, so the overall length of the content region may not be a multiple of 8-bits wide.

### 12.3.7.1 Length of Simple Elements with Textual Representation

*Textual data* is defined to mean either data of type string or data where the dfdl:representation property is 'text'.

For a textual element, the dfdl:lengthUnits property can be either 'bytes' or 'characters'.

#### 12.3.7.1.1 Text Length Specified in Bytes

If a textual element has dfdl:lengthUnits of 'bytes', and the dfdl:encoding is not SBCS, then it is possible for a partial character encoding to appear after the code units of the characters. In this case, the following rules apply:

- When parsing, as many characters as possible are extracted from the bytes of the simple content region. Any left-over bytes are skipped. (They are considered part of the grammar RightFill region).
- When unparsing, if the simple content region is larger than the encoded length of the element (as padded when dfdl:textPadKind is not 'none') then the remaining bytes, which are insufficient to hold another character code, are filled with dfdl:fillByte (Again, this is the grammar RightFill region.)

It is a Schema Definition Error if type is xs:string and dfdl:textPadKind is not 'none' and dfdl:lengthUnits is 'bytes' and dfdl:encoding is not an SBCS encoding and the XSD minLength facet is not zero. This prevents a scenario where validation against the XSD minLength facet is in characters, but padding would be performed in bytes.
12.3.7.2 Length of Simple Elements with Binary Representation

This section discusses the dfdl:lengthKind 'explicit' and 'prefixed' specified lengths for the different binary representations. When dfdl:lengthKind is 'implicit', see Section 12.3.3 dfdl:lengthKind 'implicit'.

The dfdl:lengthUnits can be 'bytes' or 'bits' unless otherwise stated. It is Schema Definition Error if dfdl:lengthUnits is 'characters'.

It is a Schema Definition Error if the specified dfdl:length for an element of dfdl:lengthKind 'explicit' is a string literal integer such that the length of the data exceeds the capacity of the simple type.

It is a Processing Error if the specified length for an element of dfdl:lengthKind 'prefixed' or 'explicit' (with dfdl:length an expression) is an integer such that the length of the data exceeds the capacity of the simple type.

12.3.7.2.1 Length of Base-2 Binary Number Elements

Non-floating point numbers with binary representation and dfdl:binaryNumberRep 'binary' are represented as a bit string which contains a base-2 representation.

The value of the specified length is constrained per the table below. The lengths are expressed in bits and are inclusive.

<table>
<thead>
<tr>
<th>Type</th>
<th>Minimum value of length</th>
<th>Maximum value of length</th>
</tr>
</thead>
<tbody>
<tr>
<td>xs:byte</td>
<td>2</td>
<td>8</td>
</tr>
<tr>
<td>xs:short</td>
<td>2</td>
<td>16</td>
</tr>
<tr>
<td>xs:int</td>
<td>2</td>
<td>32</td>
</tr>
<tr>
<td>xs:long</td>
<td>2</td>
<td>64</td>
</tr>
<tr>
<td>xs:unsignedByte</td>
<td>1</td>
<td>8</td>
</tr>
<tr>
<td>xs:unsignedShort</td>
<td>1</td>
<td>16</td>
</tr>
<tr>
<td>xs:unsignedInt</td>
<td>1</td>
<td>32</td>
</tr>
<tr>
<td>xs:unsignedLong</td>
<td>1</td>
<td>64</td>
</tr>
<tr>
<td>xs:nonNegativeInteger</td>
<td>1</td>
<td>Implementation-dependent (but not less than 64)</td>
</tr>
<tr>
<td>xs:integer</td>
<td>2</td>
<td>Implementation-dependent (but not less than 64)</td>
</tr>
<tr>
<td>xs:decimal</td>
<td>$8^{39}$</td>
<td>Implementation-dependent (but not less than 64)</td>
</tr>
</tbody>
</table>

Table 23: Allowable Specified Lengths in Bits for Base-2 Binary Number Elements

See Section 13.7.1.1 Converting Base-2 Binary Numbers for details of the conversion to/from numeric values.

12.3.7.2.2 Length of Floating Point Binary Number Elements

For binary elements of types xs:float or xs:double, a specified length must be either exactly 4 bytes or exactly 8 bytes respectively.

The dfdl:lengthUnits property must be 'bytes'. It is a Schema Definition Error otherwise.

39 Type decimal must be a minimum of 8 bits because lengthUnits 'bits' is not allowed for xs:decimal.
See Section 13.8 Properties Specific to Float/Double with Binary Representation.

**12.3.7.2.3 Length of Packed Decimal Number Elements**

Non-floating-point numbers with binary representation and `dfdl:binaryNumberRep 'packed', 'bcd', or 'ibm4690Packed',` are represented as a bit string of 4 bit nibbles. The term *packed decimal* is used to describe such numbers.

It is a Schema Definition Error if the specified length is not a multiple of 4 bits.

The maximum specified length of a packed decimal number is implementation-defined.

See Section 13.7 Properties Specific to Number with Binary Representation for details of the conversion of the packed decimal bit string to/from a numeric value.

**12.3.7.2.4 Length of Binary Boolean Elements**

The specified length of a binary element of type `xs:boolean` is as for type `xs:unsignedInt` described in Section 12.3.7.2.1 Length of Base-2 Binary Number Elements.

See also Section 13.10 Properties Specific to Boolean with Binary Representation for details of how the data is converted to/from a Boolean value.

**12.3.7.2.5 Length of Base-2 Binary Calendar Elements**

Calendars (types `date`, `time`, `dateTime`) with binary representation and `dfdl:binaryCalendarRep 'binarySeconds' or 'binaryMilliseconds'` are represented as a bit string which contains a base-2 representation. The specified length must be either exactly 4 bytes or exactly 8 bytes respectively.

The `dfdl:lengthUnits` property must be 'bytes'. It is a Schema Definition Error otherwise.

See Section 13.13 Properties Specific to Calendar with Binary Representation for details of how the data is converted to/from the calendar type.

**12.3.7.2.6 Length of Packed Decimal Calendar Elements**

Calendars (types `date`, `time`, `dateTime`) with binary representation and `dfdl:binaryCalendarRep 'packed', 'bcd', or 'ibm4690Packed',` are represented as a bit string of 4-bit nibbles. The term *packed decimal* is used to describe such calendars.

It is a Schema Definition Error if the specified length is not a multiple of 4 bits.

The maximum specified length of a packed decimal calendar is implementation-defined (but not less than 9 bytes, which corresponds to calendar pattern 'yyyyMMddhhmmsSSS')

See Section 13.13 Properties Specific to Calendar with Binary Representation for details of how the data is converted to/from the calendar type.

**12.3.7.2.7 Length of Binary Opaque Elements**

The `dfdl:lengthUnits` property must be 'bytes'. It is a Schema Definition Error otherwise.

When unparsing a specified length element of type `xs:hexBinary`, and the simple content region is larger than the length of the element in the Infoset, then the remaining bytes are filled using the `dfdl:fillByte` property.

The `dfdl:fillByte` is not used to trim an element of type `xs:hexBinary` when parsing.

**12.3.7.3 Length of Complex Elements**

A complex element of specified length is defining a 'box' in which its child elements exist. An example of this would be a fixed-length record element with a variable number of children.

---

40 This is the smallest pattern that contains all the digit-only symbols. SSS is the minimum precision that must be supported for fractional seconds, but in can be more, hence why 'not less than 9 bytes'.
elements. The dfdl:lengthUnits may be 'bytes' or 'characters' and it is a Schema Definition Error otherwise.

It is possible that the children may not entirely fill the full length of the complex element. An example is a complex element with a specified length of 100 characters, which contains a sequence of child elements that use up less than 100 characters of data, perhaps because an optional element is not present. In this case the remaining unused data is called the ElementUnused region in the data syntax grammar of Section 9.2. Another example is a complex element with a specified length of 100 bytes, which contains a sequence of child elements the last of which has dfdl:lengthKind 'endOfParent', dfdl:representation 'text' and a multi-byte dfdl:encoding such that the element does not use up all the bytes of data. In this case the remaining unused bytes comprise the child element's RightFill region in the data syntax grammar of Section 9.2. In both examples, the unused area is skipped when parsing, and is filled with the dfdl:fillByte on unparsing.

Note that a poorly chosen value for dfdl:fillByte may fill the region with data that cannot be decoded in the character set encoding, resulting in a decode error when this data is subsequently parsed again. When dfdl:lengthUnits is 'characters' the value for dfdl:fillByte must be chosen to avoid this error.
13 Simple Types
The dfdl:representation property identifies the physical representation of the element as text or binary. For some of the simple type and representation combinations there are additional properties that specify a further refinement of the representation.
These properties are described in relation to the logical type groupings of the simple types into Number, String, Calendar, Boolean, and Opaque groups, per Section 5.1 DFDL Simple Types.

13.1 Properties Common to All Simple Types

<table>

### The dfdl:escapeScheme Properties

The `dfdl:escapeScheme` annotation is used within a `dfdl:defineEscapeScheme` annotation to group the properties of an escape scheme and allows a common set of properties to be defined that can be reused.

An escape scheme is needed when the content of a text element contains sequences of characters that are the same as an in-scope separator or terminator. If the characters are not escaped, a parser scanning for a separator or terminator would erroneously find the character sequence in the content.

An escape scheme defines the properties that describe the text escaping rules. There are two variants on such schemes:

- The use of a single escape character to cause the next character to be interpreted literally. The escape character itself is escaped by the escape-escape character.
- The use of a pair of escape strings to cause the enclosed group of characters to be interpreted literally. The ending escape string is escaped by the escape-escape character.

On parsing, the escape scheme is applied after pad characters are trimmed and on unparsing before pad characters are added. A pad character is not escaped by an escape character. When parsing, pad characters are trimmed without reference to an escape scheme. When unparsing, pad characters are added without reference to an escape scheme.

On unparsing, the application of escape scheme processing takes place before the application of the `dfdl:emptyValueDelimiterPolicy` property.

</tbody>
</table>

Valid values 'escapeCharacter', 'escapeBlock'

The type of escape mechanism defined in the escape scheme

When 'escapeCharacter': On unparsing a single character of the data is escaped by adding a dfdl:escapeCharacter or dfdl:escapeEscapeCharacter immediately before it. The characters to escape are determined by property dfdl:escapeCharacterPolicy. On parsing any in-scope terminating delimiter encountered in the data is not interpreted as such when it is immediately preceded by the dfdl:escapeCharacter (when not itself preceded by the dfdl:escapeEscapeCharacter). Occurrences of the dfdl:escapeCharacter and dfdl:escapeEscapeCharacter are removed from the data as determined by property dfdl:escapeCharacterPolicy, unless the dfdl:escapeCharacter is preceded by the dfdl:escapeEscapeCharacter, or the dfdl:escapeEscapeCharacter does not precede the dfdl:escapeCharacter, respectively.

When 'escapeBlock': On unparsing the entire data are escaped by adding dfdl:escapeBlockStart to the beginning and dfdl:escapeBlockEnd to the end of the data. The data is either always escaped or escaped when needed as specified by dfdl:generateEscapeBlock. If the data is escaped and contains the dfdl:escapeBlockEnd then first character of each appearance of the dfdl:escapeBlockEnd is escaped by the dfdl:escapeEscapeCharacter.

On parsing the dfdl:escapeBlockStart string must be the first characters in the (trimmed) data in order to activate the escape scheme. The dfdl:escapeBlockStart string is removed from the beginning of the data. Until a matching dfdl:escapeBlockEnd string (that is, one not preceded by the dfdl:escapeEscapeCharacter) is found in the data, any in-scope terminating delimiter encountered in the data is not interpreted as such, and any dfdl:escapeEscapeCharacters are removed when they precede a dfdl:escapeBlockEnd string. The matching dfdl:escapeBlockEnd string is removed from the data. The matching dfdl:escapeBlockEnd does not have to be the last character(s) in the (trimmed) data in order to de-activate the escape scheme. A dfdl:escapeBlockStart occurring anywhere in the data other than the first characters has no significance.

Annotation: dfdl:escapeScheme
- The DFDL byte value entity ( %#rXX; ) is not allowed
- DFDL Character classes NL, WSP, WSP+, WSP*, and ES are not allowed

It is a Schema Definition Error if the string literal contains any of the disallowed constructs.

Escape characters contribute to the simple value region (SimpleLogicalValue or NilLiteralValue) of the field Annotation: dfdl:escapeScheme

<tr>
<td>If the empty string is specified then no escaping of escape characters occurs.</td>
<td></td>
</tr>
</tbody>
</table>
It is explicitly allowed for both the dfdl:escapeCharacter and the dfdl:escapeEscapeCharacter to be the same character. In that case processing functions as if the dfdl:escapeCharacter escapes itself. Escape-escape characters contribute to the simple value region (SimpleLogicalValue or NilLiteralValue) of the field.

During unparsing the following are escaped as described in `dfdl:escapeKind` when they are in the data:

- Any in-scope terminating delimiter by escaping its first character.
- `dfdl:escapeCharacter` (escaped by `dfdl:escapeEscapeCharacter`)

During parsing, occurrences of `dfdl:escapeCharacter` and `dfdl:escapeEscapeCharacter` are interpreted and removed from the data as described in `dfdl:escapeKind`, except that `dfdl:escapeCharacter` is only removed when it immediately precedes an in-scope terminating delimiter. Annotation: `dfdl:escapeScheme`

**Table 27 Escape Scheme Properties**

13.2.1.1 Escape Scheme Example

Consider a `dfdl:escapeScheme` annotation with the following properties:

- `dfdl:escapeBlockStart="start"`
- `dfdl:escapeBlockEnd="end"`
- `dfdl:escapeEscapeCharacter="#"`

If this is used to serialize a DFDL Infoset element of type `xs:string` with value "A hash is a #", then the value is wrapped with the `dfdl:escapeBlockStart` and `dfdl:escapeBlockEnd`, giving simple content "startA hash is a #end". If this data is parsed, the "#end" is treated as an escaped escape block end and the parse fails with a Processing Error, reporting that there is no escape block end in the data.

In this scenario, the data is not compliant with the escape scheme, and the DFDL unparser MUST issue a Processing Error.

Additional examples are in Appendix A: Escape Scheme Use Cases.

13.3 Properties for Bidirectional support for All Simple Types with Text representation

Bidirectional text is a feature expected in a future revision of the DFDL standard.

<table>

<table>
<thead>
<tr>
<th>Property Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>textStringJustification</td>
<td>Enum</td>
</tr>
<tr>
<td></td>
<td>Valid values 'left', 'right', 'center'</td>
</tr>
<tr>
<td></td>
<td>Unparsing: 'left': Justifies to the left and adds padding chars to the string contents if the string is too short, to the length determined by the <code>dfdl:textPadKind</code> property.</td>
</tr>
</tbody>
</table>
'right': Justifies to the right and adds padding chars to the string contents if the string is too short, to the length determined by the dfdl:textPadKind property.

'center': Adds equal padding chars left and right of the string contents if the string is too short, to the length determined by the dfdl:textPadKind property. It adds one extra padding char on the left if needed.

Parsing:

'left': Trims any pad characters from the right of the string, according to dfdl:textTrimKind property.

'right': Trims any pad characters from the left of the string, according to dfdl:textTrimKind property.

'center' Trims any pad characters from the left and right of the string, according to dfdl:textTrimKind property.

Annotation: dfdl:element, dfdl:simpleType

textStringPadCharacter

DFDL String Literal

The value that is used when padding or trimming string elements.

The value can be a single character or a single byte.

If a character, then it can be specified using a literal character or using DFDL entities.

If a byte, then it must be specified using a single byte value entity otherwise it is a Schema Definition Error

If a pad character is specified when dfdl:lengthUnits is 'bytes' then the pad character must be a single-byte character.

If a pad byte is specified when dfdl:lengthUnits is 'characters' then

- the encoding must be a fixed-width encoding
- padding and trimming must be applied using a sequence of N pad bytes, where N is the width of a character in the fixed-width encoding.

Padding Character Restrictions: The string literal is restricted to allow only certain kinds of DFDL String Literal syntax:

- DFDL character entities are allowed
- The DFDL byte value entity ( %#rXX; ) is allowed.
- DFDL Character classes NL, WSP, WSP+, WSP*, and ES are not allowed

It is a Schema Definition Error if the string literal contains any of the disallowed syntax.

Annotation: dfdl:element, dfdl:simpleType

truncateSpecifiedLengthString

Enum

Valid values are 'yes', 'no'

Used on unparsing only.

'yes' means if the logical type is xs:string and the value is longer than the specified length, the string is truncated to this length. (See Section 12.3.7 Elements of Specified Length.) No Processing Error is raised.
This property is needed when a DFDL schema has specified lengths for strings. The strings in an Infoset being unparsed do not necessarily fit within those specified lengths. This property provides the means to express whether this is an error, or the strings can be truncated to fit.

The position from which data is truncated is determined by the value of the dfdl:textStringJustification property. If the value of the dfdl:textStringJustification property is 'left', data is truncated from the right; if the value of the dfdl:textStringJustification property is 'right', data is truncated from the left. However, if the value of the dfdl:textStringJustification property is 'center', truncation does not occur, and a Processing Error occurs if the value is too long.

When unparsing, Validation Errors cannot be prevented by truncation as validation takes place on the augmented Infoset, before any truncation has occurred.

Table 29 Properties Specific to String

13.5 Properties Specific to Number with Text or Binary Representation

There are many properties for describing textual number representations. The properties deal with the representation of the numeric value only. Other symbols adjacent to the textual representation of a number, such as currency symbols, percent signs, or coordinate axis indicators, are not considered part of the value representation.

<table>
<thead>
<tr>

<tr>
<td></td>
<td>'standard' means represented as characters in the character set encoding specified by the dfdl:encoding property.</td>
</tr>
<tr>
<td></td>
<td>'zoned' means represented as a zoned decimal in the character set encoding specified by the dfdl:encoding property. In zoned representation each decimal digit is stored in one character code point (usually 1 byte), with the least-significant four bits encoding the digit value 0 through 9. The most-significant four bits, called the</td>
</tr>
</tbody>
</table>
"zone" bits, are usually set to a fixed value. Typically these zone bits are hex F in EBCDIC encodings or 3 in ASCII encodings so that the byte holds a character value corresponding to the digit. However, in the first or last character code the zone bits are modified to represent the sign of the number. This is called overpunched sign since zoned representation originated when computers used punched cards for data.

Which characters are used to represent modified ('overpunched') positive and negative signs varies by encoding, COBOL compiler, and system. The code points are fixed for EBCDIC systems but not for ASCII.

In EBCDIC-based encodings, code points 0xC0 to 0xC9 or 0x0F0 to 0xF9 represent a positive sign and digits 0 to 9 (these byte ranges correspond typically to characters '{ABCDEFGHI' or '0123456789'), and code points 0xD0 to 0xD9 or 0xB0 to 0xB9 represent a negative sign and digits 0 to 9 (these byte ranges correspond typically to characters 'JKLMNOPQR' or '¶£¥·©§¶¼½¾ '). On parsing both ranges are accepted. On unparsing the range 0xC0 to 0xC9 are produced for positive signs and the range 0xD0 to 0xD9 are produced for negative signs.

For ASCII-based encodings see the property dfdl:textZonedSignStyle.

Zoned is not supported for float and double numbers. Base 10 is assumed, and the encoding must be for an EBCDIC or ASCII compatible encoding. It is a Schema Definition Error if any of these requirements are not met.

<table>
<thead>
<tr>
<th>Annotation: dfdl:element, dfdl:simpleType</th>
</tr>
</thead>

</tr>
<tr>
<td>If a pad byte is specified when dfdl:lengthUnits is 'characters' then</td>
</tr>
<tr>
<td>- the encoding must be a fixed-width encoding</td>
</tr>
</tbody>
</table>
- padding and trimming must be applied using a sequence of N pad bytes, where N is the width of a character in the fixed-width encoding.

When parsing, if the pad character is '0' and dfdl:textTrimKind is 'padChar' then the SimpleContent region is trimmed of the '0' characters as defined by the trimming rules. If at least one '0' character is removed and the trimmed text causes a Processing Error when parsed, a single '0' character is re-instated, and the text is parsed again. This is to handle the case when '0' characters are trimmed away leaving no digits. This rule also applies when the pad character is a DFDL character entity equivalent to '0'. This rule does not apply when the pad character is any other character nor when a pad byte is specified.

The string literal value is restricted in the same way as described in "Pad Character Restrictions" in the description of the dfdl:textStringPadCharacter property.

**Text Number Character Restrictions**

**dfdl:textNumberPattern** contains a grouping separator symbol (it is a Schema Definition Error otherwise.) Empty string is not an allowable value.

This property can be computed by way of an expression which returns a DFDL String Literal that represents a single character. The expression must not contain forward references to elements which have not yet been processed.

The string literal value is restricted in the same way as described in “Text Number Character Restrictions” in the description of the `dfdl:textStandardDecimalSeparator` property.

See also Section 13.6.1.1 `dfdl:textNumberPattern` for `dfdl:textNumberRep 'standard'` for additional details about grouping separators.

Annotation: `dfdl:element`, `dfdl:simpleType`  

---

**textStandardExponentRep**

DFDL String Literal or DFDL Expression

Defines the actual character(s) that appear in the data as the exponent indicator. If the empty string is specified then no exponent character is used.

This property is applicable when `dfdl:textNumberRep` is 'standard' and `dfdl:textStandardBase` is 10. Empty string is an allowable value, so that formats like NNN+M (meaning NNN x 10 with MM exponent) can be expressed.

This property must be set even if the `dfdl:textNumberPattern` does not contain an 'E' (exponent) character. It is a Schema Definition Error if this property is not set or in scope for any number with `dfdl:representation 'text'`.

This property can be computed by way of an expression which returns a DFDL String Literal. The expression must not contain forward references to elements which have not yet been processed.

The string literal value is restricted in the same way as described in “Text Number Character Restrictions” in the description of the `dfdl:textStandardDecimalSeparator` property.

If `dfdl:ignoreCase` is 'yes' then the case of the string is ignored by the parser.

Annotation: `dfdl:element`, `dfdl:simpleType`  

---

**textStandardInfinityRep**

DFDL String Literal

The value used to represent infinity.

Infinity is represented as a string with the positive or negative prefixes and suffixes from the `dfdl:textNumberPattern` applied.

This property is applicable when `dfdl:textNumberRep` is 'standard', `dfdl:textStandardBase` is 10 and the simple type is float or double.

If `dfdl:ignoreCase` is 'yes' then the case of the string is ignored by the parser.

The string literal value is restricted in the same way as described in “Text Number Character Restrictions” in the
description of the dfdl:textStandardDecimalSeparator property.
It is a Schema Definition Error if empty string found as the
property value.
Annotation: dfdl:element, dfdl:simpleType

<table>
<thead>
<tr>
<th>textZonedSignStyle</th>
<th>Enum</th>
</tr>
</thead>
<tbody>
<tr>
<td>Specifies the code points that are used to modify the sign nibble of the byte containing the sign, when the dfdl:encoding is an ASCII-derived character set encoding. The location of this sign nibble is indicated in the dfdl:textNumberPattern. This property is applicable when dfdl:textNumberRep is 'zoned'. Used only when dfdl:encoding is an ASCII-derived character set encoding. The encoding must provide the character to single byte code point mapping used by the specified value of dfdl:textZonedSignStyle, as stated below. Valid values 'asciiStandard', 'asciiTranslatedEBCDIC', 'asciiCAReliaModified', and 'asciiTandemModified' Which characters are used to represent modified (also called 'overpunched') positive and negative signs, varies by encoding, COBOL compiler, and system. The code points are fixed for EBCDIC systems but not for ASCII. In ASCII-based encodings, this property is used to determine how signs are expressed for zoned numbers.</td>
<td></td>
</tr>
</tbody>
</table>

- asciiStandard: ASCII characters '0123456789' represent a positive sign and the corresponding digit. (Sign nibble for '+' is 0x3, which is the high nibble of these code points unmodified.) ASCII characters 'pqrstuvwxy' represent negative sign and digits 0 to 9. (Code points 0x70 to 0x79)
- asciiTranslatedEBCDIC: The overpunched character is the ASCII equivalent of the typical EBCDIC above. So, the characters '{ABCDEFGHI' still represent a positive sign and digits 0 to 9. (These are code points 0x7B, 0x41 through 0x49). The characters '}JKLMNOPQR' still represent negative sign and digits 0 to 9. (These are code points 0x7D, 0x4A through 0x52). This case comes up if EBCDIC zoned decimal data is translated to ASCII as if it were textual data.)
• asciiCARealiaModified41: In this style, the ASCII characters '0123456789' represent positive sign and digits 0 to 9 as in asciiStandard. However, ASCII characters from code points 0x20 to 0x29 are used for negative sign and the corresponding decimal digit. This doesn't translate well into printing characters. These characters include the space (" ") for zero, characters '!'"#$%&' for 1 through 6, the single quote character '"' for 7, and the parenthesis '(' for 8 and 9.

• asciiTandemModified: In this style the ASCII characters '0123456789' represent positive sign and digits 0 to 9, but code points 0x80 to 0x89 are used to represent negative sign and a digit. There are no corresponding code points in the standard ASCII encoding since these values are all above 128 (decimal). This means the resultant bytes are not code points in standard ASCII, so the schema must specify an encoding like ISO-8859-1 for such zoned decimals to parse without an encoding error. (Note that neither ISO-8859-1 encoding, nor Unicode have assigned glyphs for these code points. They are considered control characters.)

---

41 Reference for this CA Realia 0x20 overpunch for negative sign is the article: "EBCDIC to ASCII Conversion of Signed Fields" [CARealia] where it says:

COBOL compilers that run on ASCII platforms have a "signed" data type that operates in a similar manner to the EBCDIC Signed field -- that is, they over punch the sign on the LSD (Least Significant Digit). However, this is not standardized in ASCII, and different compilers use different overpunch codes. For example, Computer Associates’ Realia compiler uses a 30 hex for positive values and a 20 hex for negative values, but Micro Focus® and Microsoft® use 30 hex for positive values and 70 hex for negative values.
13.6.1.1 dfdl:textNumberPattern for dfdl:textNumberRep 'standard'

When dfdl:textNumberRep is 'standard' this property only applies when dfdl:textStandardBase is 10.

The pattern comes in two parts separated by a semi-colon. The first is mandatory and applies to positive numbers, the second is optional and applies to negative numbers.

Examples: The first shows digits/fractions and positive/negative signs, the second shows exponent, the third shows virtual decimal point, the fourth shows scaling position.

```
+###,##0.00;(###,##0.00)

##0.0#E0
000V00
PPP0000
```

The "V" symbol is used to indicate the location of an implied decimal point for fixed point number representations. (This is an extension to the ICU pattern language.)

The "P" symbol is used to indicate that a decimal scaling factor needs to be applied. (This is an extension to the ICU pattern language.)

The actual grouping separator, decimal separator and exponent characters are defined independently of the pattern.

The actual positive sign and negative sign are defined within the pattern itself.

Many characters in a pattern are taken literally; they are matched during parsing and output unchanged during unparsing. Special characters, on the other hand, stand for other characters, strings, or classes of characters. For example, the '#' character is replaced by a digit.

To insert a special character in a pattern as a literal, that is, without any special meaning, the character must be quoted. There are some exceptions to this which are noted below.

</tbody>
</table>

**Table 32 dfdl:textNumberPattern Special Characters**

A pattern contains a positive and negative subpattern, for example, "#,##0.00;(#,##0.00)". Each subpattern has a prefix, a numeric part, and a suffix. If there is no explicit negative subpattern, the negative subpattern is the minus sign prefixed to the positive subpattern. That is, "0.00" alone is equivalent to "0.00;−0.00". If there is an explicit negative subpattern, it serves only to specify the negative prefix and suffix; the number of digits, minimal digits, and other characteristics are ignored in the negative subpattern. That means that "#,##0.0#;(#)" has precisely the same result as "#,##0.0#:;(#,##0.0#)".

The prefixes, suffixes, and various symbols used for infinity, digits, grouping separators, decimal separators, etc. may be set to arbitrary values, and they appear properly during unparsing. However, care must be taken that the symbols and strings do not conflict, or parsing will be unreliable. For example, either the positive and negative prefixes or the suffixes must be distinct for parse to be able to distinguish positive from negative values.

The *grouping separator* is a character that separates clusters of integer digits to make large numbers more legible. It commonly used for thousands, but in some locales it separates ten-thousands. The *grouping size* is the number of digits between the grouping separators, such as 3 for "100,000,000" or 4 for "1 0000 0000". There are two different grouping sizes: One used for the least significant integer digits, the *primary grouping size*, and one used for all others, the *secondary grouping size*. In most locales these are the same, but sometimes they are different. For example, if the primary grouping interval is 3, and the secondary is 2, then this corresponds to the pattern "#,##,##0", and the number 123456789 is formatted as "12,34,56,789". If a pattern contains multiple grouping separators, the interval between the last one and the end of the integer defines the primary grouping size, and the interval between the last two defines the secondary grouping size. All others are ignored, so "#,##,##,####" == "####,####,####" == "##,####,####,####".

The P symbol is used to derive the location of an assumed decimal point when the point is not within the number that appears in the data. It acts as a decimal scaling factor.

The symbol P can be specified only as a continuous string of Ps in the leftmost or rightmost digit positions in the vinteger region of the pattern.

It is a Schema Definition Error if any symbols other than "0", "1" through "9" or # are used in the vinteger region of the pattern.

**Examples**

<table>
<thead>
<tr>
<th>Data Representation</th>
<th>Pattern</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>123</td>
<td>PP000</td>
<td>0.00123</td>
</tr>
<tr>
<td>123</td>
<td>000PP</td>
<td>12300</td>
</tr>
</tbody>
</table>

**Table 33 Examples of P Symbol in the dfdl:textNumberPattern Property**

```
pattern := subpattern (';' subpattern)?
subpattern := prefix? ((number exponent?)| vpinteger) suffix?
number := (integer ('.' fraction)?) | sigdigits
vpinteger := pinteger | (vinteger exponent?)
pinteger := ('P' integer) | (integer 'P' )
vinteger := ('V' integer) |
            ('
"####",####,####" == "##,####,####,####".

The P symbol is used to derive the location of an assumed decimal point when the point is not within the number that appears in the data. It acts as a decimal scaling factor.

The symbol P can be specified only as a continuous string of Ps in the leftmost or rightmost digit positions in the vinteger region of the pattern.

It is a Schema Definition Error if any symbols other than "0", "1" through "9" or # are used in the vinteger region of the pattern.

**Examples**

X* 0 or more instances of X
X? 0 or 1 instances of X
X|Y either X or Y
C..D any character from C up to D, inclusive
S-T characters in S, except those in T

Figure 4 dfdl:textNumberPattern BNF syntax

The first subpattern is for positive numbers. The second (optional) subpattern is for negative numbers.

Not indicated in the BNF syntax above:

- The grouping separator ',', can occur inside the integer region, between any two pattern characters of that region, as long as the number region is not followed by an exponent region.
- Two grouping intervals are recognized: That between the decimal point and the first grouping symbol, and that between the first and second grouping symbols. These intervals are identical in most locales, but in some locales they differ. For example, the pattern "#.##,###" formats the number 123456789 as "12,34,56,789".
- The pad specifier padSpec may appear before the prefix, after the prefix, before the suffix, after the suffix, or not at all.
- In place of '0', the digits '1' through '9' in the number or vpinteger region may be used to indicate a rounding increment.

The term maximum fraction digits is the total number of '0' and '#' characters in the fraction sub-pattern above.
The term minimum fraction digits is the total number of '0' characters (only) in the fraction sub-pattern above.
The term maximum integer digits is a limit that is implementation-dependent but MUST be at least 20 (which is the number of digits in a base 10 unsigned long).42
The term minimum integer digits is the total number of '0' characters (only) in the integer sub-pattern above.

- A pattern with a V symbol must not have # symbols to the right of the V symbol.
- A pattern with P symbols at the left end must not have # symbols.
- A pattern with P symbols at the right end can have # symbols.
- A pattern with a V symbol must not have @ or * symbols.
- A pattern with P symbols must not have @ or E or * symbols.

Parsing
During parsing, grouping separators are removed from the data.

Unparsing

42 Implementations which use current versions of the popular ICU library will allow 309 digits as maximum integer digits.
Unparsing is guided by several parameters all of which can be specified using a pattern. The following description applies to formats that do not use scientific notation.

If the number of actual integer digits exceeds the maximum integer digits, then only the least significant digits are output. For example, 1997 is formatted as "97" if the maximum integer digits are 2.

If the number of actual integer digits is less than the minimum integer digits, then leading zeros are added. For example, 1997 is formatted as "01997" if the minimum integer digits are 5.

If the number of actual fraction digits exceeds the maximum fraction digits, then half-even rounding is performed to the maximum fraction digits. For example, 0.125 is formatted as "0.12" if the maximum fraction digits are 2. This behavior can be changed by specifying a rounding increment and a rounding mode.

If the number of actual fraction digits is less than the minimum fraction digits, then trailing zeros are added. For example, 0.125 is formatted as "0.1250" if the minimum fraction digits are 4.

Trailing fractional zeros are not output if they occur positions after the decimal, where \( j \) is less than the maximum fraction digits. For example, 0.10004 is formatted as "0.1" if the maximum fraction digits are four or less.

**Special Values**

NaN is represented as a string determined by the dfdl: textStandardNaNRep property. This is the only value for which the prefixes and suffixes are not used.

Infinity is represented as a string with the positive or negative prefixes and suffixes applied. The infinity string is determined by the dfdl: textStandardInfinityRep property.

**Scientific Notation**

Numbers in scientific notation are expressed as the product of a mantissa and a power of ten, for example, 1234 can be expressed as \( 1.234 \times 10^3 \). The mantissa is typically in the half-open interval \([1.0, 10.0)\) or sometimes \([0.0, 1.0)\), but it need not be. In a pattern, the exponent character immediately followed by one or more digit characters indicates scientific notation. Example: "0.###E0" formats the number 1234 as "1234E3".

The number of digit characters after the exponent character gives the minimum exponent digit count. There is no maximum. Negative exponents are formatted using the minus sign, not the prefix and suffix from the pattern. This allows patterns such as "0.###E0 m/s". To prefix positive exponents with a plus sign, specify '+' between the exponent and the digits: "0.###E+0" produces data like "1E+1", "1E+0", "1E-1", etc.

The minimum number of integer digits is achieved by adjusting the exponent. Example: 0.00123 formatted with "00.###E0" yields "12.3E-4". This only happens if there is no maximum number of integer digits. If there is a maximum, then the minimum number of integer digits is fixed at one.

The maximum number of integer digits, if present, specifies the exponent grouping. The most common use of this is to generate engineering notation, in which the exponent is a multiple of three, e.g., "###0.###E0". The number 12345 is formatted using "###0.#####E0" as "12.345E3".

When using scientific notation, the formatter controls the digit counts using significant digits logic. The maximum number of significant digits limits the total number of integer and fraction digits that are shown in the mantissa; it does not affect parsing. For example, 12345 formatted with "###0.#####E0" is "12.3E3".

Exponential patterns must not contain grouping separators.

**Significant Digits**

The '@' pattern character can be used with the '#' to control how many integer and fraction digits are needed to display the specified number of significant digits. The '@' only affects unparsing behavior. Examples:

<table>
<thead>
<tr>
<th>Pattern</th>
<th>Minimum significant digits</th>
<th>Maximum significant digits</th>
<th>Number</th>
<th>Formatted Output</th>
</tr>
</thead>
<tbody>
<tr>
<td>@@@</td>
<td>3</td>
<td>3</td>
<td>12345</td>
<td>12300</td>
</tr>
</tbody>
</table>
Table 34 Significant Digits '@' Symbol in the dfdl:textNumberPattern Property

<table>
<thead>
<tr>
<th>Pattern</th>
<th>Min Digits</th>
<th>Max Digits</th>
<th>Value 1</th>
<th>Value 2</th>
</tr>
</thead>
<tbody>
<tr>
<td>@@@@</td>
<td>3</td>
<td>3</td>
<td>0.12345</td>
<td>0.123</td>
</tr>
<tr>
<td>@@##</td>
<td>2</td>
<td>4</td>
<td>3.14159</td>
<td>3.142</td>
</tr>
<tr>
<td>@@##</td>
<td>2</td>
<td>4</td>
<td>1.23004</td>
<td>1.23</td>
</tr>
</tbody>
</table>

Significant digit counts may be expressed using patterns that specify a minimum and maximum number of significant digits. These are indicated by the '@' and '#' characters. The minimum number of significant digits is the number of '@' characters. The maximum number of significant digits is the number of '@' characters plus the number of '#' characters following on the right. For example, the pattern "@@@" indicates exactly 3 significant digits. The pattern "@##" indicates from 1 to 3 significant digits. Trailing zero digits to the right of the decimal separator are suppressed after the minimum number of significant digits have been shown. For example, the pattern "@##" formats the number 0.1203 as "0.12".

If a pattern uses significant digits, it must not contain a decimal separator, nor the '0' pattern character. Patterns such as "@00" or "@.###" are disallowed.

Any number of '#' characters may be prepended to the left of the leftmost '@' character. These have no effect on the minimum and maximum significant digits counts but may be used to position grouping separators. For example, "##.##" indicates a minimum of one significant digit, a maximum of two significant digits, and a grouping size of three.

The number of significant digits has no effect on parsing.

Significant digits may be used together with exponential notation. For example, the pattern "@@###E0" is equivalent to "0.0###E0".

The '@' pattern character can be used only in 'standard' textNumberRep (not 'zoned') and excludes the 'P' and 'V' pattern characters. It is a Schema Definition Error if the '@' pattern character appears in 'zoned' textNumberRep, or in conjunction with the 'P' or 'V' pattern characters.

Padding

Padding may be specified through the pattern syntax. In a pattern the pad escape character, followed by a single pad character, causes padding to be parsed and formatted. The pad escape character is '*'. For example, "**#,.00" formats 123 to "xx123.00", and 1234 to "1,234.00". When padding is in effect, the width of the positive subpattern, including prefix and suffix, determines the format width. For example, in the pattern "** #0 o'clock", the format width is 10.

The width is counted in 16-bit code units.

Some parameters which usually do not matter have meaning when padding is used, because the pattern width is significant with padding. In the pattern "** ###,.###0.###", the format width is 14. The initial characters "###," do not affect the grouping size or maximum integer digits, but they do affect the format width.

Padding may be inserted at one of four locations: before the prefix, after the prefix, before the suffix, or after the suffix. If there is no prefix, before the prefix and after the prefix are equivalent, likewise for the suffix.

When specified in a pattern, the 32-bit codepoint immediately following the pad escape is the pad character. This may be any character, including a special pattern character. That is, the pad escape escapes the following character. If there is no character after the pad escape, then the pattern is illegal.

Note: Padding specified through the pattern syntax is distinct from, and in addition to, padding specified using dfdl:textPadKind.

Rounding

How rounding is controlled is given by dfdl:textNumberRounding. The rounding increment may be specified in the dfdl:textNumberPattern itself using digits '1' through '9' or using an explicit
increment in dfdl:textNumberRoundingIncrement. For example, 1230 rounded to the nearest 50 is 1250. 1.234 rounded to the nearest 0.65 is 1.3.

- Rounding only affects the string produced by unparsing. It does not affect parsing or change any numerical values.
- In a pattern, digits '1' through '9' specify rounding, but otherwise behave identically to digit '0'. For example, "#.50" specifies a rounding increment of 50.
- Using digits in a pattern, rounding is always 'half even', meaning rounds towards the nearest integer, or towards the nearest even integer if equidistant.

Using an explicit rounding increment, dfdl:textNumberRoundingMode determines how values are rounded.

13.6.1.2 dfdl:textNumberPattern for dfdl:textNumberRep 'zoned'
When dfdl:textNumberRep is 'zoned' a subset of the number pattern language described in Section 13.6.1.1 dfdl:textNumberPattern for dfdl:textNumberRep 'standard' is used. Only the pattern for positive numbers is used. It is a Schema Definition Error if the negative pattern is specified.

In addition, only the following pattern characters may be used:

- '+' must be present at the beginning or end of the pattern to indicate whether the leading or trailing digit carries the overpunched sign, if the logical type is signed
- '+' may be present at the beginning or end of the pattern to indicate whether the leading or trailing digit carries the overpunched sign, if the logical type is unsigned. If logical type is unsigned and dfdl:textNumberPolicy 'lax' specified it is a Schema Definition Error if no '+' is present.
- 'V' may be used to indicate the location of an implied decimal point
- 'P' may be used to indicate the decimal scaling
- '0-9' indicates the number of needed digits (including overpunched).
- '#' indicates the number of optional digits.

Rounding occurs as described under Rounding in 13.6.1.1 dfdl:textNumberPattern for dfdl:textNumberRep 'standard'

13.6.2 Converting logical numbers to/from text representation

- Signed numbers with dfdl:textNumberRep 'standard' and dfdl:textStandardBase 10 are mapped using the dfdl:textNumberPattern.
- Signed numbers with dfdl:textNumberRep 'standard' and dfdl:textStandardBase not 10 are mapped to an unsigned representation. On unparsing the minimum number of characters to represent the digits is output and it is a Processing Error if the value is negative.
- Signed numbers with dfdl:textNumberRep 'zoned' are mapped using the dfdl:textNumberPattern to indicate the position of the sign and virtual decimal point. On parsing if the sign is not overpunched, that is it does not have a sign, it is treated as positive. On unparsing the sign is always overpunched.
- Unsigned numbers with dfdl:textNumberRep 'standard' and dfdl:textStandardBase 10 are mapped using the dfdl:textNumberPattern. On parsing it is a Processing Error if the data are negative.
- Unsigned numbers with dfdl:textNumberRep 'standard' and dfdl:textStandardBase not 10 are mapped to an unsigned representation. On unparsing the minimum number of characters to represent the digits is output.
- Unsigned numbers with dfdl:textNumberRep 'zoned' are mapped using the dfdl:textNumberPattern to indicate the position of the sign and virtual decimal point. On parsing it is a Processing Error if the data are negative. On unparsing the data are not overpunched with a sign.
13.7 Properties Specific to Number with Binary Representation

These properties are applicable to simple type xs:decimal and its derived types which include all the signed and unsigned integer types. These properties are not applicable to types xs:float and xs:double. See Section 13.8. Note that simple types derived from xs:decimal do not imply base-10 representations in the data stream.

<table>

</tr>
</tbody>
</table>

- 'packed' means represented as an IBM 390 packed decimal. Each byte contains two decimal digits, except for the least significant byte, which contains a sign in the least significant nibble.
- 'bcd' means represented as a binary coded decimal with two digits per byte.
- 'binary' means represented as twos complement for signed types and unsigned base-2 binary for unsigned types.

Note that the maximum allowed value for twos-complement and unsigned base-2 binary integers is implementation-dependent but MUST be at least that of a xs:long type, which is the equivalent of an 8 byte/64-bit signed integer.

- 'ibm4690Packed' is a variant of a packed decimal having the following characteristics:
  - Nibbles represent digits 0 - 9 in the usual BCD manner.
  - A positive value is simply indicated by digits.
  - A negative number is indicated by digits with the most significant nibble being xD.
  - If a positive or negative value packs to an odd number of nibbles, an extra XF nibble is added as the most significant nibble.

For all values, the dfdl:byteOrder property is used to determine the numeric significance of the bytes making up the representation, and the dfdl:bitOrder property is used to determine the numeric significance of the bits within a byte.

<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>binaryDecimalVirtualPoint</td>
<td>Integer.</td>
</tr>
<tr>
<td></td>
<td>Used when base simpleType is xs:decimal.</td>
</tr>
</tbody>
</table>
An integer that represents the position of an implied decimal point within a number or specify 0.
If specified as 0 then there is no virtual decimal point.
If specified as a positive integer, the position of the decimal point is moved from the least-significant side of the number toward the most-significant side of the number. For example, if 3 is specified then, the integer value 1234 represents 1.234. This is equivalent to dividing by $10^3$.
If specified as a negative integer, the position of the decimal point is moved from the least significant side of the number further in the less-significant direction. For example, if specified as -3, the integer value 1234 represents 1234 000. This is equivalent to multiplying by $10^3$.
When unparsing, if the property value is not sufficient to remove the decimal point from the Infoset value, it is a Processing Error. This is true even if the resultant number can be converted into an integer (that is, all digits after the decimal point are zero) because it is an example of excess precision where no rounding is possible.

Table 35 Properties Specific to Number with Binary Representation
13.7.1 Converting Logical Numbers to/from Binary Representation

When unparsing a binary number (packed decimal or two's-complement) and excess precision is supplied in the Infoset no rounding occurs. It is a Processing Error.

13.7.1.1 Converting Base-2 Binary Numbers

For both parsing and unparsing, the bit string that represents the content region for a base-2 binary number is converted to/from an Infoset value by a calculation that involves the length and the dfdl:byteOrder and dfdl:bitOrder properties.

When parsing, DFDL specifies how an unsigned integer of unbounded magnitude is computed from a bit string based on its length, and the dfdl:byteOrder and dfdl:bitOrder properties. For signed types, this unbounded integer is converted into a signed value by way of the well-known two's-complement scheme, and for the xs:decimal type, the dfdl:binaryDecimalVirtualPoint property can be used to convert this integer into a decimal value with an integer and a fractional component.

A DFDL implementation can use any conversion technique consistent with this description.

13.7.1.2 Bit strings, Alignment, and dfdl:fillByte

The dfdl:alignmentUnits of 'bits', and dfdl:alignment of '1' can be used to position a bit string anywhere in the data stream without regard for any other grouping of bits into bytes.

The numeric value of the unsigned integer represented by a bit string is unaffected by alignment.

When unparsing a bit string, alignment may cause the bits within the bit string to occupy only some of the bits within a byte of the data stream. The bits of data in the alignment fill region are unspecified by the elements of the DFDL schema, and when parsing, neither they, nor any data computed from them are put into the DFDL Infoset. During unparsing, such unspecified bits are filled in using the value of the dfdl:fillByte property. Corresponding bits from the dfdl:fillByte value are used to fill in unspecified bits of the data stream. That is, if bit K (K is 1 or greater, but less than or equal to 8) of a data stream byte is unspecified, its value is taken from bit K of the dfdl:fillByte property value.

Since the value of any bit string element is unaffected by alignment, the logical unsigned integer value for a bit-string is always computed as if the first bit were at position 1 of the bit stream. If the dfdl:length for the bit-string evaluates to M, then the bit-string conceptually occupies bits 1 to M of a data stream for purposes of computing its value.

13.7.1.3 Bits within Bit Strings of Length <= 8

Any time the length in bits, M, is < 8, then when set, the bit at position Z, starting from the most-significant bit, (typically written on the left) supplies value $2^{(M-Z)}$, and the value of the bit string as an integer is the sum of these values for each of its bits.

13.7.1.4 Bits within Bit Strings of Length > 8

Call M the length of the bit string element in bits. In general, when $M > 8$ the contribution of a bit in position i to the numeric value of a bit string is given by a formula specific to the dfdl:byteOrder.

For dfdl:byteOrder of 'bigEndian' the value of bit i is given by $2^\left(\text{M} - \text{i}\right)$, where i = 1 is the index of the most-significant bit.

For dfdl:byteOrder of 'littleEndian' the value of bit i is given by a more complex formula. The following pseudo code computes the value of a bit in a littleEndian bit string. It is just a very big expression but is spread out over many local variables to illustrate the various sub-calculations clearly. DFDL implementations MAY use any way of converting bit strings to the corresponding integer values that is consistent with this:

In the pseudo code below:

- '%' is modular division (division where remainder is returned)
- '/' is regular division (quotient is returned)
- the expression 'a ? b : c' means 'if a is true, then the value is b, otherwise the value is c'

The pseudo code is as follows:
littleEndianBitValue(bitPosition, bitStringLength)
assert bitPosition >= 1;
assert bitStringLength >= 1;
assert bitStringLength >= bitPosition;
numBitsInFinalPartialByte = bitStringLength % 8;
numBitsInWholeBytes = bitStringLength - 
numBitsInFinalPartialByte;
bitPosInByte = ((bitPosition - 1) % 8) + 1;
widthOfActiveBitsInByte = (bitPosition <= numBitsInWholeBytes) 
? 8 : numBitsInFinalPartialByte;
placeValueExponentOfBitInByte = widthOfActiveBitsInByte - 
bitPosInByte;
bitValueInByte = 2^placeValueExponentOfBitInByte;
byteNumZeroBased = (bitPosition - 1)/8;
scaleFactorForBytePosition = 2^(8 * byteNumZeroBased);
bitValue = bitValueInByte * scaleFactorForBytePosition;
return bitValue;

Figure 5 Little Endian bit position and value

13.7.1.4.1 Examples of Unsigned Integer Conversion
Consider the first three bytes of the data stream. Imagine their numeric values as 0x5A 0x92 0x00.

| Positions: | 00000000 01111111 11122222 | 12345678 90123456 78901234 |
| Bits:      | 01011010 10010010 00000000 | 5 A 9 2 0 0 |

Beginning at bit position 1, (the very first bit) considering the first two bytes as a bigEndian short, the value is 0x5A92.

As a littleEndian short, the value is 0x925A.

Examining a bit string of length 13, beginning at position 2:
One can examine the same data stream and consider the bit positions that make up element 'x', which are the bits at positions 2 through 14 inclusive.

```
<xs:sequence>
  ... 
</xs:sequence>
```

Since alignment does not affect logical value, one obtains the same logical value as if the bits were realigned. That is, the value is the same as if the bits of the element's representation began with bit position 1.

```
Realigned Positions:
00000000 01111111 11222222
12345678 90123456 78901234
Bits:
10110101 00100
```

The DFDL schema fragment above gives element 'x' the `dfdl:byteOrder 'bigEndian'` property and the `dfdl:bitOrder 'mostSignificantBitFirst'` property. In this case the place value of each position is given by $2^{M-i}$. Below the bit values are lined up underneath their place-values.

```
Place value of bits
...11110 00000000
...21098 76543210
Bit values
...10110 10100100
Hex values
  1  6  A  4
```

The value of element 'x' is 0x16A4. Notice how it is the most-significant byte -- which is the first byte when big endian -- that becomes the partial byte (having fewer than 8 bits) in the case where the length of the bit string is not a multiple of 8 bits.

For `dfdl:byteOrder` of 'littleEndian'. The place values of the individual bits are not as easily visualized. However there is still a basic formula (given in the pseudo code in Section 13.7.1.4 Bits within Bit Strings of Length > 8) and value.

Looking again at our realigned positions:

```
Realigned Positions:
00000000 01111111 11222222
12345678 90123456 78901234
Bits:
10110101 00100
```

The place values of each of these bits, for little endian byte order can be seen to be:

```
PlaceValue positions
00000000 ...11100
76543210 ...21098
Bit values
```
One must reorder the bytes for little endian byte order. The value of element 'x' is 0x04B5. In little endian form, the first 8 bits make up the first byte, and that contains the least-significant byte of the logical numeric unsignedShort value. The additional bits of the partial byte are once again the most significant byte; however, for little endian form, this is the second byte. The second byte contains only 5 bits, and they are the most significant bits within that byte, but they are treated as if shifted to become the least significant 5 bits of a logical byte that contributes to the integer value. This logical byte makes up the most-significant byte of the unsignedShort integer.

Now examine the 13 bits beginning at position 2, in the context where dfdl:byteOrder is 'littleEndian' and dfdl:bitOrder is 'leastSignificantBitFirst' and dfdl:binaryNumberRep is 'binary'.

In this case, the bit positions are assigned differently. Below the bytes are shown left-to-right:

<table>
<thead>
<tr>
<th>Hex values</th>
<th>B 5 0 4</th>
</tr>
</thead>
</table>

The bits of interest are highlighted above. Redisplaying this same data, but reversing the order of the bytes to right-to-left, then one gets:

<table>
<thead>
<tr>
<th>Hex values</th>
<th>5 A 9 2 0 0</th>
</tr>
</thead>
</table>

The above shows more clearly the contiguous region of bits containing:

| 0 1001 0010 1101 |

or the value 0x092D.

### 13.7.1.5 Converting Packed Decimal Numbers

Signed numbers with dfdl:binaryNumberRep 'packed' are parsed using a nibble to indicate the sign. The unsigned nibble is treated as positive. On unparsing the sign nibble is written according to dfdl:binaryPackedSignCodes. The unsigned nibble is never written.

Signed numbers with dfdl:binaryNumberRep 'bcd' are always positive. On unparsing it is a Processing Error if the Infoset data is negative.

Signed numbers with dfdl:binaryNumberRep 'ibm4690Packed' are parsed using the sign nibble to identify negative values. There is no sign nibble for positive values. On unparsing the nibble 0xD is written for negative values.

Unsigned numbers with dfdl:binaryNumberRep 'packed' are parsed if the nibble is positive or unsigned. It is a Processing Error if the data is negative. On unparsing the unsigned nibble is used.

Unsigned numbers with dfdl:binaryNumberRep 'bcd' are readily parsed as BCD data is always positive.

Unsigned numbers with dfdl:binaryNumberRep 'ibm4690Packed' are parsed if there is no sign nibble of 0xD to identify a negative value. It is a Processing Error if the data is negative. On unparsing no sign nibble is written.

</tr>
<tr>
<td></td>
<td>If dfdl:ignoreCase is 'yes' then the case of the string is ignored by the parser.</td>
</tr>
</tbody>
</table>

43 Note that XSD 1.1 moved to IEEE 754-2008 only because of new decimal support, and not for enhanced float support. That's why in XSD 1.1 there are still just the xs:float and xs:double built-in types. Any future support for half-precision and quad-precision in XSD would very likely be implemented by adding new built-in types that derive from xs:anySimpleType. It is likely therefore that future DFDL support for half-precision and quad-precision will build on XSD.
### Text Boolean Character Restrictions
The string literal is restricted to allow only certain kinds of DFDL String Literal syntax:
- DFDL character entities are allowed
- The DFDL byte value entity ( %#rXX; ) is not allowed.
- DFDL Character classes NL, WSP, WSP+, WSP*, and ES are not allowed

It is a Schema Definition Error if the string literal is the empty string or contains any of the disallowed constructs.

</table>
| calendarPatternKind      | Enum      | Valid values 'explicit', 'implicit'
                             - 'explicit' means the pattern is given by dfdl:calendarPattern, 'implicit' means the pattern is derived from the XML schema date/time type.   |
|                          |           | **Logical Type** | **Default Pattern**                                                                                                                                |
| xs:date                  |           | yyyy-MM-dd                                                                                                                                  |
| xs:dateTime              |           | yyyy-MM-dd'T'HH:mm:ss                                                                                                                        |
| xs:time                  |           | HH:mm:ssZ                                                                                                                                   |
|                          |           | Annotation: dfdl:element, dfdl:simpleType                                                                                            |
| calendarCheckPolicy      | Enum      | Valid values 'strict', 'lax'
                             - Indicates how lenient to be when parsing against the pattern. 
                             - See Section 13.11.2 The dfdl:calendarCheckPolicy Property below for details of the specific behaviors for 'strict' and 'lax'. |
|                          |           | Annotation: dfdl:element, dfdl:simpleType                                                                                            |
| calendarTimeZone         | String    | This property provides the time zone that is assumed if no time zone explicitly occurs in the data.
                             - Valid values specify a UTC time zone offset by matching the regular expression:
                             - (UTC) ([+-]([01][d]|[d])(([[:][0-5][d]{1,2})?))?
                             - In addition, empty string can be specified to indicate "no time zone" which simply leaves the time zone unknown/unspecified.
                             - Data which does not specify a time zone does not obtain a time zone from this property and so simply lacks time zone information.
                             - The IANA time zone format (also known as the Olson time zone format) may also be used. (e.g., America/New_York) See [IANATimeZone].
                             - Note that this property is used when parsing only. 
                             - Annotation: dfdl:element, dfdl:simpleType                                                                 |
| calendarObserveDST       | Enum      | Valid values 'yes', 'no'
                             - Whether the time zone given in dfdl:calendarTimeZone observes daylight savings time.
                             - Ignored if dfdl:calendarTimeZone is specified in UTC format, or if dfdl:calendarTimeZone is empty string. That is, this property is used only if the dfdl:calendarTimeZone is in IANA (also known as Olson) format [IANATimeZone].
                             - This property applies to parsing only. 
                             - Annotation: dfdl:element, dfdl:simpleType                                                                 |
| calendarFirstDayOfWeek   | Enum      | Valid values 'Monday' ... 'Sunday'
                             - The day of the week upon which a new week is considered to start.                                    |
### calendarDaysInFirstWeek

**Non-negative Integer**

Valid values 1 to 7

Specify the number of days of the new year that must fall within the first week.

The start of a year usually falls in the middle of a week. If the number of days in that week is less than the value specified here, the week is considered to be the last week of the previous year; hence week 1 starts some days into the new year. Otherwise it is considered to be the first week of the new year; hence week 1 starts some days before the new year.

**Annotation:** dfdl:element, dfdl:simpleType

### calendarCenturyStart

**Non-negative Integer**

Valid values 0 to 99.

This property determines on parsing how two-digit years are interpreted. It specifies the two digits that start a 100-year window that contains the current year. For example, if 89 is specified, and the current year is 2006, all two-digit dates are interpreted as being in the range 1989 to 2088. A two-digit year less than 89 is interpreted as 20nn and a two-digit year more than or equal to 89 is treated as 19nn.

**Annotation:** dfdl:element, dfdl:simpleType

### calendarLanguage

**String or DFDL Expression**

The language that is used when the pattern produces a presentation in text such as for names of the months, and names of days of the week.

The value must match the regular expression:

```
([A-Za-z]{1,8})([_-][A-Za-z0-9]{1,8})*
```

It is a Schema Definition Error otherwise.

The expression must not contain forward references to elements which have not yet been processed.

All DFDL Implementations MUST support dfdl:calendarLanguage value "en".

DFDL implementations MAY support additional values, however, the value of the dfdl:calendarLanguage property is always interpreted as a Unicode Language Identifier as defined by [LDML], and [CLDR].

**Annotation:** dfdl:element, dfdl:simpleType

</tbody>
</table>
The count of pattern letters determines the format as indicated in the table. When numeric fields abut one another directly, with no intervening delimiter characters, they constitute a run of abutting numeric fields. Such runs are parsed specially as described at [ICUDateTime].

The maximum number of "S" symbols that may appear in the pattern is implementation-defined but MUST be at least three. The stored accuracy for fractional seconds is also implementation-defined but MUST be at least millisecond accuracy. When the number of "S" symbols in a pattern exceeds the supported accuracy, excess fractional seconds are truncated from the right (not rounded) when parsing, and zeros are added to the right when unparsing. For example, a DFDL processor allows up to six "S" symbols and has millisecond accuracy; for pattern "ss.SSSSSS", data "12.345678" would be parsed into Infoset xs:time "00:00:12:345", which would be unparsed into data "12.345000".

Unlike other fields, fractional seconds, "S", are padded on the right with zero.

It is a Processing Error if seconds appear in that part of the SimpleContent region that represents a time zone.

The count of pattern letters determines the format as indicated in the table. If dfdl:representation is text, any characters in the pattern that are not in the ranges of ['a'..'z'] and ['A'..'Z'] are treated as quoted text. For instance, characters like ':', '.', ' ', '#' and '@' appear in the formatted output even if they are not embraced within single quotes. The single quote is used to 'escape' letters. Two single quotes in a row, whether inside or outside a quoted sequence, represent a 'real' single quote.

If dfdl:representation is binary, then the pattern can contain only characters and symbols that always result in the presentation of digits.

The symbols ‘z’, ‘zz’, and ‘zzz’ have identical meaning, as do ‘Z’, ‘ZZ’, and ‘ZZZ’.

The ‘I’ symbol must not be used with any other symbol except for ‘escape for text’. It represents calendar formats that match those defined in the restricted profile of the ISO 8601 standard proposed by the W3C at [http://www.w3.org/TR/NOTE-datetime]. The formats are referred to as 'granularities'.

- xs:dateTime. When parsing, the data must match one of the granularities. When unparsing, the fullest granularity is used.
- xs:date. When parsing, the data must match one of the date-only granularities. When unparsing, the fullest date-only granularity is used.
- xs:time. When parsing, the data must match only the time components of one of the granularities that contains time components. When unparsing, the time components of the fullest granularity are used. The literal 'T' character is not expected in the data when parsing and is not output when unparsing.
- The number of fractional second digits supported is the same as for the "S" fractional seconds specifier described above.
- The omission of time zone from the input data when the type is xs:dateTime or xs:time is not a Processing Error. If that occurs then the time zone is obtained from the calendarTimeZone property.
- When unparsing and the time zone is UTC, the time zone is output as ‘+00:00’.

When parsing, for any pattern that omits components the values for the omitted components are supplied from the Unix epoch 1970-01-01T00:00:00.000.44

44 Note that DFDL does not support an isolated month, day, or year that is not part of a greater date type, as it does not support the XSD simple types xs:gMonth, xs:gDay, and xs:gYear.
When unparsing, and the pattern contains a formatting symbol that requires a component of the date/time and the Infoset value does not contain that component, it is a Processing Error.

When parsing a calendar element with a packed decimal representation then the nibbles from the data are converted to text digits without any trimming of leading or trailing zeros, and the result is then matched against the pattern according to the usual rules.

When unparsing, if a time zone symbol is not available for a particular time zone, a fallback may be used as defined in [ICUDateTime].

13.11.2 The dfdl:calendarCheckPolicy Property

The differences in behavior between 'strict' and 'lax' for this property can be subtle. Both are quite lenient in enforcement of many variations in format, with the 'lax' value adding additional tolerance of more format variations to those already allowed by the 'strict' value.

1. Lenient parsing behaviour when in 'strict' policy:
   a. Case insensitive matching for text fields
   b. MMM, MMMM, and MMMMM all accept either short or long form of Month
   c. E, EE, EEE, EEEE, EEEEE, and EEEEEE all accept either abbreviated, full, narrow and short forms of Day of Week
   d. Accepts truncated leftmost numeric field (e.g., pattern "HHmmss" allows "123456" (12:34:56) and "23456" (2:34:56) but not "3456")

2. Additional lenient parsing behaviour when in 'lax' policy is implementation-defined, but typically includes:
   a. Values outside valid ranges are normalized (e.g., "March 32 1996" is treated as "April 1 1996")
   b. Ignoring a trailing dot after a non-numeric field
   c. Leading and trailing whitespace in the data but not in the pattern is accepted
   d. Whitespace in the pattern can be missing in the data
   e. Partial matching on literal strings. E.g., data "20130621d" allowed for pattern "yyyyMMdd'date'"

13.12 Properties Specific to Calendar with Text Representation

<table>
<thead>

<td>DFDL String Literal</td>
</tr>
<tr>
<td></td>
<td>The value that is used when padding or trimming calendar elements. The value</td>
</tr>
<tr>
<td></td>
<td>can be a single character or a single byte.</td>
</tr>
<tr>
<td></td>
<td>If a character, then it can be specified using a literal character or</td>
</tr>
<tr>
<td></td>
<td>using DFDL entities.</td>
</tr>
<tr>
<td></td>
<td>If a byte, then it must be specified using a single byte value entity</td>
</tr>
<tr>
<td></td>
<td>If a pad character is specified when dfdl:lengthUnits is 'bytes' then</td>
</tr>
<tr>
<td></td>
<td>the pad character must be a single-byte character.</td>
</tr>
<tr>
<td></td>
<td>If a pad byte is specified when dfdl:lengthUnits is 'characters' then</td>
</tr>
<tr>
<td></td>
<td>• the encoding must be a fixed-width encoding</td>
</tr>
</tbody>
</table>
• padding and trimming must be applied using a sequence of N pad bytes, where N is the width of a character in the fixed-width encoding.

The string literal value is restricted in the same way as described in "Pad Character Restrictions" in the description of the dfdl:textStringPadCharacter property.

Annotation: dfdl:element, dfdl:simpleType

Table 41 Properties Specific to Calendar with Text Representation

13.13 Properties Specific to Calendar with Binary Representation

<table>
<thead>
<tr>
<th>Property Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>binaryCalendarRep</td>
<td>Enum</td>
</tr>
<tr>
<td></td>
<td>Valid values are 'packed', 'bcd', 'ibm4690Packed', 'binarySeconds', 'binaryMilliseconds'</td>
</tr>
</tbody>
</table>

For all values, the dfdl:byteOrder property is used to determine the numeric significance of the bytes making up the representation.

• 'packed' means represented as an IBM 390 packed decimal. Each byte contains two decimal digits, except for the rightmost byte, which contains a sign to the right of a decimal digit. The digits are interpreted according to the dfdl:calendarPattern property. Property dfdl:binaryPackedSignCodes is applicable.

• 'bcd' means represented as a binary coded decimal with two digits per byte. The digits are interpreted according to the dfdl:calendarPattern property

• 'ibm4690Packed' means represented as a variant of packed format as described in property dfdl:binaryNumberRep. The digits are interpreted according to the dfdl:calendarPattern property.

For all packed decimals, property dfdl:binaryNumberCheckPolicy is applicable.

For all these packed decimals, dfdl:calendarPattern can contain only characters and symbols that always result in the presentation of digits. It is a Schema Definition Error otherwise. This implies that property dfdl:calendarPatternKind must be 'explicit' because the default patterns for 'implicit' contain non-numeric characters. It is a Schema Definition Error otherwise.

See Section 13.7 Properties Specific to Number with Binary Representation.

Note also that a virtual decimal point for the boundary between seconds and fractional seconds is implied from the pattern at the boundary of 's' and 'S', i.e., where the substring 'sS' appears in the pattern.

• 'binarySeconds' means represented as binary xs:int, that is, as a 4 byte signed integer that is the number of seconds from the epoch (positive or negative). It is a Schema Definition Error if there is a specified length not equivalent to 4 bytes.

• 'binaryMilliseconds' means represented as binary xs:long, that is, as an 8 byte signed integer that is the number of milliseconds from the epoch (positive or negative). It is a Schema Definition Error if there is a specified length not equivalent to 8 bytes.
Values binarySeconds and binaryMilliseconds may only be used when the type is xs:dateTime. (It is a Schema Definition Error otherwise.)

<table>
<thead>
<tr>
<th>binaryCalendarEpoch</th>
<th>DateTime</th>
</tr>
</thead>
<tbody>
<tr>
<td>Used when dfdl:binaryCalendarRep is 'binarySeconds' or 'binaryMilliseconds'</td>
<td></td>
</tr>
<tr>
<td>The epoch from which to calculate dates and times.</td>
<td></td>
</tr>
<tr>
<td>If the time zone is omitted from the value, then UTC is used.</td>
<td></td>
</tr>
</tbody>
</table>

**Table 42 Properties Specific to Calendar with Binary Representation**

Examples of packed decimal format calendars for December 14, 1923 and dfdl:calendarPattern of 'MMddyy' would be:
- packed: (hexadecimal) 01 21 42 3C
- bcd: (hexadecimal) 12 14 23
- ibm4690Packed: (hexadecimal) 12 14 23

The 'C' nibble at the end of the 'packed' representation is a sign nibble, and the leading 0 nibble is just to align to a byte boundary.

**13.14 Properties Specific to Opaque Types (xs:hexBinary)**

There are no properties specific to opaque types.

**13.15 Nil Value Processing**

Sometimes it is desirable to represent an unused element, place-holder for unknown information, or inapplicable information explicitly with an element, rather than by the lack of an element.

For example, it may be desirable to represent a sparsely populated array of data using a distinguished nil element to fill the locations where data is absent, thereby preserving the position for the elements that are present.

As another example, it may be desirable to represent an unused simple element by a value which is not conformant to the logical type of the element.

Such cases can be represented using the DFDL nil mechanism which is based on the XML Schema nil mechanism. DFDL provides what are commonly called "in-band" nil values by way of dfdl:nilKind 'logicalValue', and also provides for two kinds of literal indicators of nil through dfdl:nilKind 'literalValue' and dfdl:nilKind 'literalCharacter'. Nil processing is used when the XSD 'nillable' property of an element is true.

DFDL allows elements of complex type to be nillable. However, to avoid the concept of a complex element having a value, which does not exist in DFDL, the only permissible nil value is the empty string, represented by the DFDL %ES; entity and using dfdl:nilKind 'literalValue'.

On parsing, an element occurrence is nil if the element has XSD nillable 'true' and the data is a nil representation as defined in Section 9.2.1. Specifically:

1. When dfdl:nilKind is 'literalValue', the NilLiteralValue region of the data stream matches any of the dfdl:nilValue values.
2. When dfdl:nilKind is 'literalCharacter', all characters in the NilLiteralCharacters region of the data stream match the dfdl:nilValue character.
3. When dfdl:nilKind is 'logicalValue', the data contains a normal representation, and the NilLogicalValue region of the data stream, converted to the element's logical type, matches any of the dfdl:nilValue values.

For dfdl:nilKind 'literalValue' or 'literalCharacter':
• Determination of whether the data is a nil representation for a literal nil happens first before any consideration of whether the representation is the empty, normal, or absent representations.

• Property `dfdl:nilValueDelimiterPolicy` controls whether matching one of the nil values also involves matching the initiator or terminator specified by the element. This gives control over whether a nil indicator may or may not also require the delimiters that a normal data element requires.

On unparsing, an element is nil if XSD nillable is 'true' AND the element information item in the augmented Infoset has the [nilled] member as true, in which case what is output to the data stream is one of the following:

1. When `dfdl:nilKind` is 'logicalValue' then the first value of `dfdl:nilValue` converted to the physical representation is output as the `NilLogicalValue` region.

2. When `dfdl:nilKind` is 'literalValue' then the first value of `dfdl:nilValue` is output as the `NilLiteralValue` region.

3. When `dfdl:nilKind` is 'literalCharacter' then the character from `dfdl:nilValue`, repeated to the needed length, is output as the `NilLiteralCharacters` region.

For `dfdl:nilKind` 'literalValue' or 'literalCharacter' then `dfdl:nilValueDelimiterPolicy` determines whether any initiator or terminator also appear surrounding the literal nil in the output data.

### 13.16 Properties for Nillable Elements

These properties are used when the XSD 'nillable' property of an element is 'true', and they control when and how the representation data are interpreted as having the logical meaning 'nil'.

<table>
<thead>
<tr>
<th>Property Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>nilKind</td>
<td>Enum</td>
</tr>
<tr>
<td></td>
<td>Valid values 'literalValue', 'logicalValue', 'literalCharacter'.</td>
</tr>
<tr>
<td></td>
<td>Used when XSD nillable is 'true'.</td>
</tr>
<tr>
<td></td>
<td>Specifies how <code>dfdl:nilValue</code> is interpreted to represent the nil value in the data stream.</td>
</tr>
<tr>
<td></td>
<td>If 'literalCharacter' then <code>dfdl:nilValue</code> specifies a single character or a single byte that, when repeated to the length of the element, is the nil value. 'literalCharacter' may only be specified for fixed-length elements, otherwise it is a Schema Definition Error.</td>
</tr>
<tr>
<td></td>
<td>If 'literalValue' then <code>dfdl:nilValue</code> specifies a list of DFDL literal strings that are the possible representations for nil.</td>
</tr>
<tr>
<td></td>
<td>If 'logicalValue' then <code>dfdl:nilValue</code> specifies a list of logical values that are the possible logical values for nil.</td>
</tr>
<tr>
<td></td>
<td>Complex elements can be nillable, but <code>dfdl:nilKind</code> can only be 'literalValue' and <code>dfdl:nilValue</code> must be &quot;%ES;&quot;. It is a Schema Definition Error otherwise.</td>
</tr>
<tr>
<td></td>
<td>Annotation: <code>dfdl:element</code></td>
</tr>
<tr>
<td>nilValue</td>
<td>List of DFDL String Literals, List of Logical Values, DFDL String Literal</td>
</tr>
<tr>
<td></td>
<td>Specifies the text strings that are the possible literal or logical nil values of the element.</td>
</tr>
<tr>
<td></td>
<td>If <code>dfdl:nilKind</code> is 'literalValue' then <code>dfdl:nilValue</code> specifies a whitespace separated list of DFDL literal strings that are the possible representations for nil. On parsing the element value is nil if the trimmed data matches one of the string literals in the list. On unparsing if the element value is nil the first string literal in the list is output.</td>
</tr>
</tbody>
</table>
If `dfdl:nilKind` is 'logicalValue' then `dfdl:nilValue` specifies a whitespace separated list of logical values that are the possible logical values for nil. On parsing the element value is nil if the data, converted to its logical type, matches any of the logical values in the list. On unparsing if the element value is nil, the first value from the list is converted to its physical representation and output.

If `dfdl:nilKind` is 'literalCharacter' then `dfdl:nilValue` specifies a single character or byte that, when repeated to the length of the element, is the nil representation. If a character, then it can be specified using a literal character or using DFDL entities. If a character is specified when `dfdl:lengthUnits` is 'bytes' then the `dfdl:nilValue` must be a single-byte character. To specify a byte, it must be specified using a single "%#r;" entity. If a byte is specified when `dfdl:lengthUnits` is 'characters' then the `dfdl:encoding` must be a fixed-width encoding.

On parsing, the element value is nil if all characters in the untrimmed data content match the `dfdl:nilValue` character. On unparsing, if the element value is nil the `dfdl:nilValue` character is output to the needed length.

There are restrictions on the string literal syntax of `dfdl:nilValue`.

When `dfdl:nilKind` is 'literalValue' and text representation:
- DFDL character entities are allowed
- The DFDL byte value entity ( %#rXX; ) is allowed
- DFDL Character classes NL, WSP, WSP+, WSP*, and ES are allowed.

When `dfdl:nilKind` is 'literal value and binary representation:
- DFDL character entities are allowed
- The DFDL byte value entity ( %#rXX; ) is allowed
- DFDL Character class ES is allowed.
- Other DFDL Character classes NL, WSP, WSP+, and WSP*, are not allowed.

When `dfdl:nilKind` is 'literalCharacter' and text representation:
- DFDL character entities are allowed
- The DFDL byte value entity ( %#rXX; ) is allowed.
- DFDL Character classes NL, WSP, WSP+, WSP*, and ES are not allowed.

When `dfdl:nilKind` is 'literalCharacter' and binary representation:
- DFDL character entities are allowed
- The DFDL byte value entity ( %#rXX; ) is allowed
- DFDL Character classes NL, WSP, WSP+, WSP*, and ES are not allowed.

`dfdl:nilValue` is sensitive to `dfdl:ignoreCase` when `dfdl:nilKind` is 'literalValue' or 'logicalValue', but not when `dfdl:nilKind` is 'literalCharacter'.

Complex elements can be nillable, but `dfdl:nilKind` can only be 'literalValue' and `dfdl:nilValue` must be "%ES;". It is a Schema Definition Error otherwise.

Annotation: `dfdl:element

| nilValueDelimiterPolicy | Enum |
Valid values are 'none', 'initiator', 'terminator' or 'both'.
Indicates that when the value nil is represented, an initiator (if one is defined), a terminator (if one is defined), both an initiator and a terminator (if defined) or neither must be present.
This property enables distinguishing the nil representation from the representation of a value or an empty representation based on presence or absence of the initiator and terminator.
Ignored if both dfdl:initiator and dfdl:terminator are "" (empty string).
Ignored if dfdl:nilKind is set to 'logicalValue' In this case the DFDL processor treats a nil representation like any other representation of the element in that it expects delimiters when parsing, outputs them when unparsing.

'initiator' indicates that, on parsing, the dfdl:initiator followed by a dfdl:nilValue indicates that a nil representation is present. It also indicates that on unparsing when the logical value is nil that the dfdl:initiator is output followed by the first dfdl:nilValue.

'terminator' indicates that, on parsing, a dfdl:nilValue followed by the dfdl:terminator indicates that a nil representation is present. It also indicates that on unparsing when the logical value is nil the first dfdl:nilValue followed by the dfdl:terminator is output.

'both' indicates that, on parsing, both the dfdl:initiator and dfdl:terminator must be present with a dfdl:nilValue to indicate that a nil representation is present. On unparsing the dfdl:initiator followed by the first dfdl:nilValue, followed by the dfdl:terminator is output.

'none' indicates that a dfdl:nilValue without any dfdl:initiator or dfdl:terminator indicates that a nil representation is present. On unparsing the first dfdl:nilValue is output without any dfdl:initiator or dfdl:terminator.

The value of dfdl:nilValueDelimiterPolicy MUST only be checked if there is a dfdl:initiator or dfdl:terminator in scope. If so, and dfdl:nilValueDelimiterPolicy is not set, it is a Schema Definition Error. If dfdl:initiator is not "" and dfdl:terminator is "" and dfdl:nilValueDelimiterPolicy is 'terminator' it is a Schema Definition Error. If dfdl:terminator is not "" and dfdl:initiator is "" and dfdl:nilValueDelimiterPolicy is 'initiator' it is a Schema Definition Error. It is not a Schema Definition Error if dfdl:nilValueDelimiterPolicy is 'both' and one or both of dfdl:initiator and dfdl:terminator is "". This is to accommodate the common use of setting 'both' as a schema-wide setting.
It is a Schema Definition Error if dfdl:nilValueDelimiterPolicy is set to 'none' or 'terminator' when the parent xs:sequence has dfdl:initiatedContent 'yes'.
Annotation: dfdl:element

<td></td>
</tr>
</tbody>
</table>
| When the conditions for applying a simple element default are satisfied, this property controls whether to set the Infoset item [nilled] boolean member, or to use the XSD default or fixed properties to obtain a data value.
This property has precedence over the XSD default and XSD fixed properties. It is only used, and must be defined, if the XSD nillable property is 'true'.

Defaulting occurs as described in Section 9.4 Element Defaults with nil as the default value. The dfdl:nilValue property must specify at least one nil value otherwise it is a Schema Definition Error. The dfdl:nilKind property may be any of its values.

Annotation: dfdl:element (simpleType)

Table 43 Properties for Nillable Elements

The DFDL element defaults processing uses XSD default, XSD fixed or dfdl:useNilForDefault to provide a default value. See Section 9.4 Element Defaults for a full description.

</tr>
</tbody>
</table>

Table 44 Properties for Sequence Groups
A sequence can have a dfdl:initiator and/or a dfdl:terminator as described earlier.

14.1 Empty Sequences
A sequence having no children is syntactically legal in DFDL. In the data stream, such a sequence can have non-zero length LeftFraming and RightFraming regions, but the SequenceContent region in between must be empty. It is a Processing Error if the SequenceContent region of an empty sequence has non-zero length when parsing.
XML schema does not define an empty sequence that is the content model of a complex type definition as effective content so any DFDL annotations on such a construct would be ignored. It is a Schema Definition Error if the empty sequence is the content model of a complex type, or if a complex type has nothing in its content model at all.
A hidden group reference is indicated in DFDL using an empty sequence such as

```xml
<xs:sequence dfdl:hiddenGroupRef="QName"/>
```

To XML Schema this is an empty sequence group; hence it is a Schema Definition Error if this appears as the model group of a complex type. Otherwise this is not considered an empty sequence, but a group reference.
14.2 Sequence Groups with Separators

Additional properties apply to sequence groups that use text delimiters to separate one occurrence of a member of the group from the next. Such a delimiter is called a separator. DFDL provides several properties that control the parsing and writing of separators, and satisfy the requirement to model sequences where:

1. A separator has alternative potential representations in the data.
2. A separator is placed before, after, or between occurrences in the data.
3. Separators are used to indicate the position of occurrences in the data.

These requirements are addressed by the properties `dfdl:separator`, `dfdl:separatorPosition` and `dfdl:separatorSuppressionPolicy`, as described below.

These properties combine to define the syntax for a sequence group with `dfdl:sequenceKind` 'ordered'. Not all combinations of the properties give rise to consistent syntax, so some combinations are disallowed and give rise to a Schema Definition Error.

In some sequences, the presence of separators alone is enough to establish occurrences within the sequence. Such a sequence is called a *positional* sequence.

**Positional sequence** - Each occurrence in the sequence can be identified by its position in the data. Typically, the components of such a sequence do not have an initiator. In some such sequences, the separators for optional zero-length occurrences may or must be omitted when at the end of the group. In DFDL, a sequence is considered positional if it contains only required elements and/or optional and array elements that have `dfdl:occursCountKind` 'implicit', 'fixed' or 'expression', and it has `dfdl:separatorSuppressionPolicy` 'never', 'trailingEmptyStrict' or 'trailingEmpty'.

**Non-positional sequence** - Occurrences in the sequence cannot be identified by their position in the data alone. Often the components of such a sequence have an initiator. Such sequences sometimes allow the separator to be omitted for optional zero-length occurrences anywhere in the sequence. Speculative parsing might need to be employed by the parser to identify each occurrence. In DFDL, a sequence is non-positional if it contains any optional or array elements that have `dfdl:occursCountKind` 'parsed' or 'stopValue', and/or it has `dfdl:separatorSuppressionPolicy` 'anyEmpty'.

<table>
<thead>
<tr>
<th>Property Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>separator</td>
<td>List of DFDL String Literals or DFDL Expression</td>
</tr>
</tbody>
</table>

Specifies a whitespace separated list of alternative DFDL String Literals that are the possible separators for the sequence. Separators occur in the data either before, between or after all occurrences of the elements or groups that are the children of the sequence, in accordance with `dfdl:separatorPosition` and `dfdl:separatorSuppressionPolicy`. Elements with `dfdl:inputValueCalc` have no representation in the data stream, and so never have an associated separator.

This property can be computed by way of an expression which returns a string of whitespace separated values. The expression must not contain forward references to elements which have not yet been processed. It is a Schema Definition Error if the expression returns an empty string.

This property can be used to determine the length of an element as described in Section 12.3.2 `dfdl:lengthKind` 'delimited'.

Each string literal in the list, whether apparent in the schema, or returned as the value of an expression, is restricted to allow only certain kinds of DFDL String Literal syntax:

- DFDL character entities are allowed.
- DFDL Byte Value entities ( %#rXX; ) are allowed.
• DFDL Character Class ES is not allowed.
• DFDL Character Classes NL, WSP, WSP+, and WSP* are allowed.
• The WSP* entity cannot appear on its own as one of the string literals in the list when determining the length of a component by scanning for delimiters.

If the above rules are not followed it is a Schema Definition Error.

The Separator, PrefixSeparator and PostfixSeparator regions contain one of the strings specified by the dfdl:separator property. When this property has "" (empty string) as its value then the separator region is of length zero.

When parsing, the list of values is processed in a greedy manner, meaning it takes all the separators, that is, each of the string literals in the whitespace separated list, and matches them each against the data. The separator with the longest match is the one that is selected as having been 'found'. Once a matching separator is found, no other matches are subsequently attempted (i.e., there is no backtracking).

On unparsing the first separator in the list is used as the separator.

If a child element uses an escape scheme, then the escape scheme also applies to any separator; hence, if the separator appears within the element value, it is escaped.

If dfdl:ignoreCase is 'yes' then the case of the string is ignored by the parser.

Table 45 Properties for Sequence Groups with Separators

14.2.1 Separators and Suppression

When parsing a sequence group that specifies a separator, the number of occurrences and separators that are expected in the data stream for a child (element or group) depends on several factors:

- Whether element occurrences are optional or required
- Whether the occurrences (element or group) have a zero-length representation
- Whether occurrences (element or group) are trailing
- Whether the sequence is positional
- The dfdl:occursCountKind of the element

Where to expect a separator for optional content of zero-length is controlled by property dfdl:separatorSuppressionPolicy.

<table>
<thead>

<td>Non-positional sequence where any occurrences that have zero length representation may be omitted from the data, along with their associated separator. It must be possible for speculative parsing to identify which elements are present.</td>
</tr>
</tbody>
</table>

Table 46 Sequence groups and separator suppression

The following are definitions for terminology used in this section:

**Potentially trailing element** – An array or optional element describes an occurrence that is said to be potentially trailing if the element can have a zero length representation and is followed in its enclosing group definition by only these kinds of schema components:

1. calculated elements (those having dfdl:inputValueCalc)
2. additional potentially trailing elements
3. potentially trailing groups

Intuitively, the array or optional element occurrence could be last.

**Potentially trailing group** – A group is said to be potentially trailing if the group has no framing and contains only potentially trailing element declarations/references, or recursively similar sequence or choice groups, and is followed in its enclosing group definition by only additional potentially trailing elements or potentially trailing groups.

**Trailing or Actually Trailing** – An element occurrence or group occurrence in the data is said to be actually trailing if it is potentially trailing and has zero-length representation and is not followed in the data by any other non-zero length element occurrence or group occurrence limited by the end of the enclosing sequence group.

In the sections that follow, it is important to remember that the dfdl:separatorSuppressionPolicy property is carried on the sequence, while the XSD minOccurs, XSD maxOccurs and dfdl:occursCountKind properties are carried on an element in that sequence.
14.2.2 Parsing Sequence Groups with Separators

Parsing child elements is described first. Parsing for child groups is described in Section 14.2.2.3. When an element is required and is not an array then one occurrence is always expected along with its separator. The dfdl:separatorSuppressionPolicy of the sequence has no effect (nothing is eligible for suppression). Otherwise the behaviour is dependent on dfdl:occursCountKind.

When dfdl:occursCountKind is 'fixed' then XSD minOccurs must equal maxOccurs and that many occurrences are always expected along with their separators. The dfdl:separatorSuppressionPolicy of the sequence has no effect (nothing is eligible for suppression).

When dfdl:occursCountKind is 'expression' the number of occurrences is given by dfdl:occursCount and exactly that many occurrences are always expected along with their separators. The dfdl:separatorSuppressionPolicy of the sequence has no effect (nothing is eligible for suppression).

When dfdl:occursCountKind is 'parsed' any number of occurrences and their separators are expected. The dfdl:separatorSuppressionPolicy of the sequence must be 'anyEmpty' and it is a Schema Definition Error otherwise.

When dfdl:occursCountKind is 'stopValue', any number of occurrences and their separators are expected followed by the stop value and its separator. The dfdl:separatorSuppressionPolicy of the sequence has no effect.

When dfdl:occursCountKind is 'implicit', between XSD minOccurs and XSD maxOccurs (inclusive) occurrences and their separators are expected, according to the dfdl:separatorSuppressionPolicy of the sequence. The behaviour for 'implicit' is more fully expressed in matrix form. The cells in the matrix give the number of occurrences of element values that are expected in the data stream when parsing, for the different values of dfdl:separatorSuppressionPolicy. The number of occurrences also depends whether XSD maxOccurs is unbounded or not, and the position of the element in the sequence. The number of separators can be inferred from this, considering dfdl:separatorPosition.

<table>

</tbody>
</table>

Table 47 Separator Suppression for dfdl:occursCountKind 'implicit' when Parsing

The notation in each cell uses the "~" symbol to mean "followed by" in the data stream. Square brackets surround things that are optional, as in they may or may not appear in the data stream. The descriptions found in the cells of the matrix do not provide a parsing algorithm, but rather state declaratively a pattern that the data must match in order to be correctly parsed.
RepDef(min) is short for "representation" and "defaultable". It means XSD minOccurs occurrences of nil, empty or normal representation. These are required occurrences, so default rules apply for empty representations. XSD minOccurs may be 0, in which case there are no required occurrences.

Rep(M) means M occurrences of nil, empty, normal or absent representation. These are optional occurrences, so default rules do not apply for empty representations.

RepNonZero(1) means an occurrence of a nil, empty or normal representation where such a representation does not have zero-length. This is an optional occurrence, so default rules do not apply.

A notation like Rep(M <= max – min) means that there are M occurrences, where M is some value between the values of the XSD minOccurs and XSD maxOccurs properties. When an unbounded number of occurrences is possible this is shown explicitly by Rep(M < INF), INF meaning infinity or unbounded.

14.2.2.1 Errors When the Sequence is Positional
In the matrix above there are some cells where the combination of properties doesn't make sense, and a Schema Definition Error is raised. These occur when an element has dfdl:occursCountKind 'implicit' and XSD maxOccurs 'unbounded', and dfdl:separatorSuppressionPolicy implies that the sequence is positional, specifically:

• If a sequence has dfdl:separatorSuppressionPolicy 'never';
• If a sequence has dfdl:separatorSuppressionPolicy 'trailingEmptyStrict' or 'trailingEmpty' and the element is not the last declaration in the sequence. (This avoids ambiguity about which element is being suppressed.)

14.2.2.2 Example Parsing Scenarios
Consider the cell of the matrix above for the element in this DFDL schema fragment:

```
<xs:sequence dfdl:separator='|' dfdl:separatorPosition='infix'
    dfdl:separatorSuppressionPolicy='trailingEmptyStrict'>
  <xs:element name='a' type='xs:int' default='0'
    maxOccurs='5' minOccurs='0'
    dfdl:representation='text' dfdl:textNumberPattern='#0'
    dfdl:occursCountKind='implicit'
    dfdl:initiator='[' dfdl:terminator=']'
    dfdl:emptyValueDelimiterPolicy='both' />
</xs:sequence>
```

Within the sequence this element 'a' is clearly potentially trailing as it is declared last. The corresponding cell in the matrix above contains this description:

\[
\text{RepDef(min)} \sim \text{Rep(M < max – min)} \sim \text{RepNonZero(1)}
\]

Since XSD minOccurs='0', the first term, RepDef(min) vanishes, leaving:

\[
\text{Rep(M < max - min)} \sim \text{RepNonZero(1)}
\]

Note Rep(M) permits absent representations, and if encountered they are simply omitted from the Infoset.

So, this data

parses and 5 items appear in the Infoset.

This data

| [1] | [2] | [3] | [4] |

45 Absent representation implies Processing Error for 'implicit' when less than or equal to XSD minOccurs.
46 Absent representation always implies zero-length. Nil, empty, and normal representations can also be zero-length with the right combinations of properties. See Section 9.2.5 Zero-length Representation.
also parses because absent representations are accepted, but only one item appears in the Infoset. (The fact that the occurrence is fourth in the array is not preserved into the Infoset). However, this data

```
[1] [1] [4]
```

causes a Processing Error because there is a final trailing separator and dfdl:separatorSuppressionPolicy is 'trailingEmptyStrict'.

Now consider the same scenario but XSD minOccurs of '2'. The first term reappears as RepDef(2). The data

```
[1] [1] [4]
```

which previously parsed successfully would now cause a Processing Error because the first two occurrences are required, so they must be either a normal representation, that is, matching xs:int syntax with surrounding initiator and terminator, or the empty representation which is [ ]. An example which parses correctly with XSD minOccurs of '2' is:

```
[1] [1] [4]
```

In this case the Infoset contains 3 items with values 1, 0, 4. The 0 value arises because the occurrence has the empty representation, the occurs index is 2 so it is required, and there is a default value 0.

If the scenario is changed so that dfdl:separatorSuppressionPolicy is 'trailingEmpty' then a different cell of the matrix above applies.

```
RepDef(min) [~ Rep(M < max – min) ]
```

This has a more lax behavior so that this data is also acceptable:

```
[1] [1] [1] [4]
```

In this case the final trailing separator is tolerated, though when unparsing this final trailing separator would not be created. This is a case where what is parsed is not exactly recreated on unparsing from the resulting Infoset, but all the information content is preserved.

Now consider the same scenario but XSD maxOccurs is 'unbounded'. In that case this data is acceptable:

```
[1] [1] [1] [1] [1] [4]
```

The Infoset values are again 1, 0, 4. But all the excess separators are tolerated.

14.2.2.3 Parsing Child Groups within Separated Sequences

When a child of a sequence is a group then a separator is expected/tolerated depending on dfdl:separatorSuppressionPolicy and other factors:

- ‘never’ - the child group’s associated separator is expected
- ‘trailingEmpty’ – if the child group is potentially trailing, has zero-length and it is actually trailing, its separator may appear or not. Additional separators are not expected.
- ‘trailingEmptyStrict’ – if the child group is potentially trailing, has zero-length and it is actually trailing, its separator must not appear.
- ‘anyEmpty’ – if the child group has zero-length its separator must not appear.

14.2.3 Unparsing Sequence Groups with Separators

Unparsing child elements is described first. Unparsing for child groups is described in Section 14.2.3.2.

When an element is required and is not an array then one occurrence is always output along with its separator. The dfdl:separatorSuppressionPolicy of the sequence has no effect (nothing is eligible for suppression).

Otherwise the behaviour is dependent on dfdl:occursCountKind.

When dfdl:occursCountKind is 'fixed' or 'expression' the occurrences in the augmented Infoset are always output along with their separators. The dfdl:separatorSuppressionPolicy of the sequence has no effect (nothing is eligible for suppression).
When dfdl:occursCountKind is 'parsed' non zero-length occurrences in the augmented Infoset are output along with their separators. The dfdl:separatorSuppressionPolicy of the sequence must be 'anyEmpty' and it is a Schema Definition Error otherwise.

When dfdl:occursCountKind is 'stopValue' the occurrences in the augmented Infoset are output along with their separators followed by the stop value and its separator, according to the dfdl:separatorSuppressionPolicy of the sequence.

When dfdl:occursCountKind is 'implicit' the occurrences in the augmented Infoset are output along with their separators, according to the dfdl:separatorSuppressionPolicy of the sequence.

The behaviour for 'implicit' is more fully expressed in matrix form. The cells in the matrix give the number of occurrences of element values that are output to the data stream when unparsing, for the different values of dfdl:separatorSuppressionPolicy. The number of occurrences also depends whether XSD maxOccurs is unbounded or not, and the position of the element in the sequence.

The number of separators output can be inferred from this, considering dfdl:separatorPosition.

<table>
<thead>
<tr>
<th>dfdl:separatorSuppressionPolicy</th>
<th>dfdl:occursCountKind 'implicit'</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Potentially Trailing</td>
</tr>
<tr>
<td></td>
<td>maxOccurs unbounded</td>
</tr>
<tr>
<td>Element not declared last</td>
<td>Element declared last</td>
</tr>
<tr>
<td>never</td>
<td>Schema definition error</td>
</tr>
<tr>
<td>trailingEmptyStrict</td>
<td>Unparse N occurrences (suppressing trailing zero-length occurrences)</td>
</tr>
<tr>
<td>trailingEmpty</td>
<td></td>
</tr>
<tr>
<td>anyEmpty</td>
<td>Unparse N occurrences (suppressing any optional zero-length occurrences)</td>
</tr>
</tbody>
</table>

Table 48 Separator Suppressions for dfdl:occursCountKind 'implicit'

The notation in each cell uses the "\(\sim\)" symbol to mean "followed by" in the output data stream. \(N\) stands for the number of elements in the augmented Infoset, which includes any defaults.

Unparse \(N\) occurrences means output \(N\) unparsed Infoset items and associated separators.

Unparse\(M\) trailing zero length occurrences means output \(M\) adjacent separators (according to dfdl:separatorPosition) as if separating \(M\) element occurrences.

(suppressing trailing zero-length reps) implies the unparsers MUST look ahead into the Infoset and determine when the representations are zero-length, and then identify those in trailing position. No separators are output corresponding to the trailing zero-length representations.

14.2.3.1 Example Unparsing Scenarios

Consider the cell of the matrix above for the element in this DFDL schema fragment:

```xml
<xs:sequence dfdl:separator='|' dfdl:separatorPosition='infix'
    dfdl:separatorSuppressionPolicy='trailingEmpty'>
    <xs:element name='a' type='xs:int'
        maxOccurs='5' minOccurs='0'
        nillable='true'
        dfdl:representation='text' dfdl:textNumberPattern='#0'
        dfdl:occursCountKind='implicit'
```
This example is similar to the one used above in the discussion of parsing with separator suppression. However, the element has no default value, the dfdl:emptyValueDelimiterPolicy has been removed, and the element is nillable. Element ‘a’ is clearly potentially trailing as it is declared last. The corresponding cell in the matrix above contains this description:

unparse N occurrences (suppressing trailing zero length reps)

Assume unparsing an Infoset containing five values: 1, 0, nil\(^{47}\), 4, nil. Five occurrences are unparsed; however, the last value is nil, which has a representation of ‘%ES;’ meaning empty-string, and dfdl:nilValueDelimiterPolicy is ‘none’ meaning no initiator or terminator is to appear in the data. Since the schema is suppressing trailing zero-length reps the unparsing results in this output:

\[
[1] | [0] | [\ ] | [4] | [\ ]
\]

This is an example where if the data is reparsed, it does not result in that original Infoset, because the trailing empty value which is the representation of the nil value, is not represented in the output, and so does not cause an Infoset item with [nilled] true to be created in the Infoset when this data is parsed. To preserve the nil, change the dfdl:nilValueDelimiterPolicy to ‘both’. In that case the output would be:

\[
[1] | [0] | [\ ] | [4] | [\ ] | [\ ]
\]

The nils now have explicit representation in the data and are recreated in the Infoset when parsing.

14.2.3.2 Unparsing Child Groups within Separated Sequences

When a child of a sequence is a group then a separator is output depending on dfdl:separatorSuppressionPolicy and other factors:

- ‘never’ - the child group’s associated separator is output
- ‘trailingEmpty’ or ‘trailingEmptyStrict’ – if the child group is potentially trailing, has zero-length and it is actually trailing, its separator is not output.
- ‘anyEmpty’ – if the child group has zero-length its separator is not output.

14.3 Unordered Sequence Groups

The occurrences of members of a sequence group with dfdl:sequenceKind of ‘unordered’ (hereafter referred to as an ‘unordered sequence’) may appear in the data in any order. Occurrences of the same member do not have to be contiguous. In the Infoset, sequence groups are always in schema order, so a DFDL processor MUST sort the members of an unordered sequence into schema order when parsing. When unparsing, the Infoset must already be in schema order, and the members of the sequence are output in schema order.

14.3.1 Restrictions for Unordered Sequences

It is a Schema Definition Error if any member of the unordered sequence is not an element declaration or an element reference.

It is a Schema Definition Error if a member of an unordered sequence is an optional element or an array element and its dfdl:occursCountKind property is not ‘parsed’

It is a Schema Definition Error if two or more members of the unordered sequence have the same name and the same namespace (see post-processing transformation below)

It is a Schema Definition Error if an unordered sequence has no members.

\(^{47}\) An Infoset item value of nil means the Infoset item [nilled] member is true, and the [dataValue] member has no value. See Section 4.2.2 Element Information Items.
14.3.2 Parsing an Unordered Sequence

When parsing, the semantics of an unordered sequence are expressed by way of:

1. a source-to-source transformation of the sequence group definition, and
2. a post-processing transformation of the Infoset.

An implementation MAY use any technique consistent with this semantic.

14.3.2.1 Source-to-source Transformation

The source-to-source transformation turns the declaration of an unordered sequence into an ordered sequence group that contains a repeating choice. To ensure that the resulting schema is a valid DFDL schema, the choice group is wrapped in an array element.

The unordered sequence is transformed as follows:

- the dfdl:sequenceKind property of the unordered sequence is changed to "ordered"
- the content of the unordered sequence is replaced by a complex element (the 'choice element') with the following properties:
  - XSD minOccurs="0"
  - XSD maxOccurs="unbounded"
  - dfdl:lengthKind "implicit"
  - dfdl:occursCountKind "parsed"
- the content of the choice element's complex type is a choice group with the following properties:
  - dfdl:choiceLengthKind "implicit"
- The members of the unordered sequence become the members of the choice group, with their declaration order preserved.
- The XSD minOccurs and XSD maxOccurs properties on each member of the choice group are both set to 1.

Using the following example as an illustration:

```xml
<xs:sequence dfdl:sequenceKind="unordered" dfdl:separator="","">
  <xs:element name="a" type="xs:string" dfdl:initiator="A:" />
  <xs:element name="b" type="xs:int" minOccurs="0" dfdl:initiator="B:" />
  <xs:element name="c" type="xs:string" minOccurs="0" maxOccurs="10" dfdl:initiator="C:" />
</xs:sequence>
```

The above unordered sequence group is conceptually rewritten into the following ordered sequence group:

```xml
<xs:sequence dfdl:sequenceKind="ordered" dfdl:separator="","">
  <xs:element name="choiceElement" minOccurs="0" maxOccurs="unbounded" dfdl:occursCountKind="parsed">
    <xs:complexType>
      <xs:choice dfdl:choiceLengthKind="implicit">
        <xs:element name="a" type="xs:string" dfdl:initiator="A:" />
        <xs:element name="b" type="xs:int" dfdl:initiator="B:" />
        <xs:element name="c" type="xs:string" dfdl:initiator="C:" />
      </xs:choice>
    </xs:complexType>
  </xs:element>
</xs:sequence>
```

Processing then constructs a temporary InfoSet for this ordered sequence group by parsing the data.

If a member element is found to have the empty representation then the parsing of that element must use the original value of XSD minOccurs. In this example, element "b" has XSD minOccurs "0" and if it is found with the empty representation then it must not be defaulted.
14.3.2.2 Post-processing Transformation

Post-processing consists of the following steps:

1. Sort the temporary Infoset to produce the real Infoset
2. Check scalar elements and validate

**Step 1: Sort the Temporary Infoset**

The temporary Infoset is transformed into the Infoset conforming to the original unordered sequence. All members of the temporary Infoset having the same name and namespace as the first child of the unordered sequence are placed first, in the order in which they were parsed. This algorithm repeats for the second child of the unordered sequence and so on until all members of the temporary Infoset have been sorted into the schema declaration order of the original unordered sequence.

For the example above, the temporary Infoset is transformed into the Infoset corresponding to:

```xml
<xs:sequence>
  <xs:element name="a" type="xs:string"/>
  <xs:element name="b" type="xs:int" minOccurs="0"/>
  <xs:element name="c" type="xs:string" minOccurs="0" maxOccurs="10"/>
</xs:sequence>
```

**Step 2: Check Scalar Elements and Validate**

For each element in the unordered sequence having XSD minOccurs "1" and maxOccurs "1", the number of occurrences is checked. Each such element must occur exactly once in the Infoset, else it is a Processing Error.

If validation is enabled, the DFDL processor validates the number of occurrences of each member of the unordered sequence against XSD minOccurs and XSD maxOccurs.

These checks are the same as those performed for an ordered sequence group. However, in an unordered sequence the checking of XSD minOccurs and XSD maxOccurs MUST be performed after the entire group has been parsed.

14.3.3 Unparsing an Unordered Sequence

When unparsing, the behavior is exactly as if dfdl:sequenceKind is 'ordered'. The members of the unordered sequence group are output in schema declaration order.

### 14.4 Floating Elements

Elements within an ordered sequence can be designated as floating which means that they can appear in any position within the sequence.48

An ordered sequence with floating components is similar to an unordered sequence except only the floating elements may be out of order.

Within an ordered sequence with floating components a non-floating array element must have its occurrences appearing contiguously, so any floating element occurrences cannot appear in between occurrences of the array element.(In other words, property dfdl:floating 'yes' only makes a statement about the floating element, not about any other elements in the sequence.)

<table>
<thead>
<tr>
<th>Property Name</th>
<th>Description</th>
</tr>
</thead>
</table>

48The NTE segment in the X12 EDI standard is an example of a floating element.
<table>
<thead>
<tr>
<th>floating</th>
<th>Enum</th>
</tr>
</thead>
<tbody>
<tr>
<td>Valid values are 'yes', 'no'</td>
<td></td>
</tr>
<tr>
<td>Whether the occurrences of an element in an ordered sequence can appear out-of-order in the representation.</td>
<td></td>
</tr>
<tr>
<td>When parsing, and dfdl:floating is 'yes', occurrences of the element may be encountered in the representation in many positions within its containing sequence. If present they are placed into the Infoset in schema declaration order. If the element repeats, occurrences do not need to be contiguous in the representation.</td>
<td></td>
</tr>
<tr>
<td>When parsing, and dfdl:floating is 'no', occurrences of the element must be in schema declaration order, and, if present, they are placed into the Infoset in schema declaration order. It is a Processing Error if instances of the element are not encountered in schema declaration order.</td>
<td></td>
</tr>
<tr>
<td>When unparsing, occurrences of the element are expected in the Infoset in schema declaration order and are output in the representation in schema declaration order. It is a Processing Error if occurrences of the element are not encountered in schema declaration order.</td>
<td></td>
</tr>
<tr>
<td>It is a Schema Definition Error if an unordered sequence or a choice contains any element with dfdl:floating 'yes'.</td>
<td></td>
</tr>
<tr>
<td>It is a Schema Definition Error if an ordered sequence contains any element with dfdl:floating 'yes' and also contains non-element component (such as a choice or sequence model group).</td>
<td></td>
</tr>
<tr>
<td>It is a Schema Definition Error if an element with dfdl:floating 'yes' is an optional element or an array element and its dfdl:occursCountKind property is not 'parsed'.</td>
<td></td>
</tr>
<tr>
<td>It is a Schema Definition Error if two or more elements with dfdl:floating 'yes' in the same group have the same name and the same namespace.</td>
<td></td>
</tr>
</tbody>
</table>

**Annotation:** dfdl:element

**Table 49 Properties for Floating Elements**

An ordered sequence of N element children with dfdl:floating 'yes' is equivalent to an unordered sequence with the same N element children with dfdl:floating 'no'.

A complex element with dfdl:floating 'yes' can have as its content model a sequence with elements that also have dfdl:floating 'yes'.

Every element in a sequence containing one or more floating elements is a point of uncertainty, similar to the way every element in an unordered sequence is a point of uncertainty.

In resolving this point of uncertainty, a parser MUST look for the element defined at that position in the schema first and only if unsuccessful with parsing that element, the parser MUST subsequently attempt to parse the floating elements in the order they are defined in the schema. As soon as any such parse is successful this resolves the point of uncertainty.

**14.5 Hidden Groups**

Some fields in the physical stream provide information about other fields in the stream and are not really part of the data. For example, a field can give the number of repeats in a following array. These fields may not be of interest to an application after the data has been parsed, and so may be removed from the Infoset on parsing by containing the element declarations for them within a hidden group. A hidden group allows elements to be defined that are not added to the Infoset on parsing and are not expected in the Infoset on unparsing.

```xml
<xs:element name="root">  
  <xs:complexType>  
    <xs:sequence>  
```

[dfdl-wg@ogf.org](mailto:dfdl-wg@ogf.org)
An element contained within the extent of a hidden group is commonly called a hidden element. Hidden elements are referenced via path expressions using the same DFDL expression that would be used if they were not hidden.

Hidden elements can (typically will) contain the regular DFDL annotations to define their physical properties and on unparsing to set their value. They are processed using the same behavior as non-hidden elements.

When the dfdl:hiddenGroupRef property is specified on an xs:sequence schema component, the appearance of any other DFDL properties on that component is a Schema Definition Error. It is also a Schema Definition Error if the sequence is not empty.

It is a Schema Definition Error if the sequence is the only thing in the content model of a complex type definition.

It is a Schema Definition Error if dfdl:hiddenGroupRef appears on a xs:group reference, that is, unlike most format properties that apply to sequences, dfdl:hiddenGroupRef cannot be combined from a xs:group reference.

A hidden group may appear within another hidden group.

<table>
<thead>
<tr>
<th>Property Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>

</tr>
<tr>
<td></td>
<td>Reference to a global model group definition. Elements within this model group are not added to the Infoset and are called hidden elements.</td>
</tr>
<tr>
<td></td>
<td>The model group within the model group definition may be a xs:sequence or xs:choice</td>
</tr>
<tr>
<td></td>
<td>It is a Schema Definition Error if the value is the empty string.</td>
</tr>
<tr>
<td></td>
<td>It is not possible to place this property in scope on a dfdl:format annotation.</td>
</tr>
</tbody>
</table>

Table 50 Properties for Hidden Groups

When unparsing a hidden group, the behaviour is the same as when elements are missing from the Infoset; that is, the default-values algorithm applies. The only difference is that if a required element does not have a default value or a dfdl:outputValueCalc then it is a Schema Definition Error instead of a Processing Error. Note that this can be checked statically.
When unparsing a hidden group, it is a Processing Error if an element information item is provided in the Infoset for a hidden element. Examples of hidden groups are in Section 17 Calculated Value Properties.
15 Choice Groups

A choice corresponds to concepts variously called variant records, multi-format records, discriminated unions, or tagged unions in various programming languages. In some contexts, choices are referred to generally as 'unions'. However, this should not be confused with XSD unions which are an unrelated concept.

The following properties are specific to xs:choice.

<table>
<thead>
<tr>
<th>Property Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>choiceLengthKind</td>
<td>Enum</td>
</tr>
<tr>
<td></td>
<td>Valid values are 'implicit', 'explicit'</td>
</tr>
<tr>
<td></td>
<td>'implicit' means the branches of the choice are not filled, so the ChoiceContent region is variable length depending on which branch appears.</td>
</tr>
<tr>
<td></td>
<td>'explicit' means that the branches of the choice are always filled to the fixed-length specified by dfdl:choiceLength, so the ChoiceContent region is fixed-length regardless of which branch appears.</td>
</tr>
<tr>
<td></td>
<td>Annotation: dfdl:choice, dfdl:group (choice)</td>
</tr>
<tr>
<td>choiceLength</td>
<td>Integer</td>
</tr>
<tr>
<td></td>
<td>Only used when dfdl:choiceLengthKind is 'explicit'.</td>
</tr>
<tr>
<td></td>
<td>Specifies the length of the choice in bytes, so the ChoiceContent region is fixed-length regardless of which branch appears. A ChoiceUnused region is therefore possible which when unparsing is filled with dfdl:fillByte.</td>
</tr>
<tr>
<td></td>
<td>Annotation: dfdl:choice, dfdl:group (choice)</td>
</tr>
<tr>
<td>initiatedContent</td>
<td>Enum</td>
</tr>
<tr>
<td></td>
<td>Valid values are 'yes', 'no'</td>
</tr>
<tr>
<td></td>
<td>When 'yes' indicates that all the branches of the choice are initiated. It is a Schema Definition Error if any children have their dfdl:initiator property set to the empty string. The branch is known to exist when its initiator has been found. Any subsequent error parsing the branch does not cause the parser to backtrack.</td>
</tr>
<tr>
<td></td>
<td>When 'no', the branches of the choice may have their dfdl:initiator property set to the empty string.</td>
</tr>
<tr>
<td></td>
<td>Annotation: dfdl:sequence, dfdl:choice, dfdl:group</td>
</tr>
<tr>
<td>choiceDispatchKey</td>
<td>DFDL Expression</td>
</tr>
<tr>
<td></td>
<td>The expression must evaluate to an xs:string. It is a Schema Definition Error if the expression returns an empty string.</td>
</tr>
<tr>
<td></td>
<td>It is a Schema Definition Error if the expression contains forward references to elements which have not yet been processed.</td>
</tr>
<tr>
<td></td>
<td>This property is used only when parsing.</td>
</tr>
<tr>
<td></td>
<td>The resultant string must match one of the dfdl:choiceBranchKey property values of one of the branches of the choice. This match is case sensitive. If so, it discriminates to that branch. The parser then goes straight to that branch, ignoring consideration of any other choice branches. No backtracking of this decision occurs if there is a subsequent Processing Error.</td>
</tr>
<tr>
<td></td>
<td>It is a Processing Error if the value of the expression does not match any of the dfdl:choiceBranchKey property values for any of the branches.</td>
</tr>
</tbody>
</table>
It is a Schema Definition Error if any choice branch does not specify a `dfdl:choiceBranchKey` in a choice that carries `choiceDispatchKey`. It is not possible to place this property in scope on a `dfdl:format` annotation.

**Annotation:** `dfdl:choice`

<table>
<thead>
<tr>
<th><strong>choiceBranchKey</strong></th>
<th><strong>List of DFDL String Literals</strong></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>This literal provides an alternate way to discriminate a choice to a branch. When the <code>dfdl:choiceDispatchKey</code> expression evaluates to a string matching one of this property's values, the choice is discriminated to this branch. The match is case sensitive.</td>
</tr>
<tr>
<td></td>
<td>It is a Schema Definition Error if individual <code>dfdl:choiceBranchKey</code> values are not unique across all branches of a choice that carries <code>dfdl:choiceDispatchKey</code>.</td>
</tr>
<tr>
<td></td>
<td>It is a Schema Definition Error if <code>dfdl:choiceBranchKey</code> is specified on a global element, or on a sequence or choice that is the child of a global group definition.</td>
</tr>
<tr>
<td></td>
<td>It is a Schema Definition Error if any choice branch does not specify a <code>dfdl:choiceBranchKey</code> in a choice that carries <code>choiceDispatchKey</code>. Byte value entities are not allowed. Character classes are not allowed. This property is only used when parsing.</td>
</tr>
<tr>
<td></td>
<td>It is not possible to place this property in scope on a <code>dfdl:format</code> annotation.</td>
</tr>
<tr>
<td></td>
<td><strong>Annotation:</strong> <code>dfdl:element</code>, <code>dfdl:sequence</code>, <code>dfdl:choice</code>, <code>dfdl:group</code></td>
</tr>
</tbody>
</table>

**Table 51 Properties for Choice Groups**

A choice can have a `dfdl: initiator` and/or a `dfdl:terminator` as described earlier.

The explanation of choices requires this terminology:

**Branch** - A branch is one of the available alternatives within a choice. A branch can be an element of simple type or complex type, or it can be an embedded sequence, choice or group reference.

**Root of the Branch** - Each branch conceptually has a single schema component at its root which is an element, sequence, choice or group reference. This component is known as the Root of the Branch.

The Root of the Branch must not be optional. That is XSD minOccurs must be greater than zero. A choice that declares no branches in the DFDL schema is a Schema Definition Error.

When processing a choice group, the parser validates any contained path expressions. If a path expression contained inside a choice branch refers to any other branch of the choice, then it is a Schema Definition Error. Note that this rule handles nested choices also. A path that navigates outward from an inner choice to another alternative of an outer choice is violating this rule with respect to the outer choice.

**15.1 Resolving Choices**

When processing a choice, there are two ways to resolve the intended branch. In one, speculative parsing is used. In the other, a constant-time direct dispatch to a branch is performed.

### 15.1.1 Resolving Choices via Speculation

Speculative resolution works as follows:

1. Attempt to parse the first branch of the choice.
2. If this fails with a Processing Error
a) If a dfdl:discriminator evaluated to true earlier on this branch then the parser is "bound" to this branch and parsing of the entire choice construct fails with a Processing Error.

b) If the branch has a dfdl:initiator and the choice has dfdl:initiatedContent ‘yes’ then the parser is "bound" to this branch and parsing of the entire choice construct fails with a Processing Error.

c) Otherwise repeat from step 1 for the next branch of the choice.

3. It is a Processing Error if the branches of the choice are exhausted.

4. If a branch is successfully parsed without error, then that branch’s Infoset becomes the Infoset for the parse of the choice construct.

5. If the branch is an element declaration having dfdl:occursCountKind='expression' or dfdl:occursCountKind='parsed', then zero instances are possible. If the branch parses successfully without a discriminator but produces no element occurrences, then the branch is considered missing, and the parser looks for the next branch.

It is not possible for variable settings to be communicated from the speculative attempt to parse a branch to any other parsing situation. The speculative effort is completely isolated. Whether it succeeds or fails, neither the parse position in the source data, nor anything in the variable memory, nor the Infoset is affected.

Nested choices can require unbounded look ahead into the data.

15.1.2 Resolving Choices via Direct Dispatch

Direct dispatch provides a constant-time dispatch to a choice branch independent of how many choice branches there are.

Direct dispatch is indicated by the dfdl:choiceDispatchKey property. This expression is evaluated to compute the string matching (case sensitive) one of the dfdl:choiceBranchKey property values of one of the choice branches.

When a match is found, it is as if a dfdl:discriminator had evaluated to true on that branch. It is selected as resolution of the choice, and there is no backtracking to try other alternative selections if a Processing Error occurs.

The dfdl:choiceBranchKey property can be placed on element references, local element declarations, local sequences, local choices, or group references. All values of dfdl:choiceBranchKey properties must be unique across all branches of a choice that carries a dfdl:choiceDispatchKey property and it is a Schema Definition Error otherwise.

Note that it is a Schema Definition Error if both dfdl:initiatedContent and dfdl:choiceDispatchKey are provided on the same choice. However, it is not an error if a discriminator exists on a choice branch along with a dfdl:choiceBranchKey.

15.1.3 Unparsing Choices

On unparsing there is the question of how one identifies the appropriate schema choice branch corresponding to the data in the Infoset. This is complicated by the fact that the children may not be elements. They may themselves be sequences or choices. The selection of the choice branch is as follows: The element in the Infoset is used to search the choice branches in the schema, in schema definition order, but without looking inside any complex elements. If the element occurs in a branch, then that branch is selected and if subsequently a Processing Error occurs, this selection is not revisited (that is, there is no backtracking). If the next element to unparse does not identify any branch of the choice, or there is no next element to unparse, then there must be a choice branch with no required elements and the first such branch would be selected for unparsing. A choice branch can consist only of a nest of model groups with no actual element content or only optional element content.

---

49 Because DFDL v1.0 does not allow recursive definitions, the notion of unbounded here is limited by the depth of the DFDL schema, so is not truly unbounded as it would be if recursion were allowed.
To avoid any unintended behavior, all the children of a choice can be modeled as elements.

15.1.3.1 Unparsing Choices in Hidden Groups

When a choice appears inside a hidden group, there are no corresponding Infoset elements as there are none for hidden groups. The first branch of the choice is unparsed. All elements contained in the branch must have default values or must have dfdl:outputValueCalc properties to compute their values, and it is a Schema Definition Error otherwise.
16 Properties for Array Elements and Optional Elements

These properties are for array elements (XSD maxOccurs >1 or unbounded) or optional elements (XSD minOccurs 0 and XSD maxOccurs 1). The properties handle a logical one-dimensional array of any simple or complex type.

Table 52 Properties for Array Elements and Optional Elements

When XSD minOccurs 1 and XSD maxOccurs 1, the above properties are not used, and the behavior is as if dfdl:occursCountKind is 'fixed' as described in Section 16.1.1.

16.1 The dfdl:occursCountKind property

16.1.1 dfdl:occursCountKind 'fixed'

The enum 'fixed' should be used when the number of occurrences is always the same. The number is provided by the XSD maxOccurs property.
When parsing, maxOccurs occurrences are expected in the data. It is a Processing Error if less than maxOccurs occurrences are found or defaulted. The parser stops looking for occurrences when maxOccurs have been found or defaulted. When maxOccurs is 0, no occurrences are looked for in the data.

When unparsing, maxOccurs occurrences are expected in the Infoset. It is a Processing Error if less than maxOccurs occurrences are found or defaulted. The processor stops looking for more occurrence in the Infoset after maxOccurs occurrences have been found. When maxOccurs is 0, no occurrences are looked for in the Infoset or written.

It is a Schema Definition Error if XSD minOccurs is not equal to XSD maxOccurs.

16.1.2 **ddfl:occursCountKind 'implicit'**

The enum 'implicit' should be used when the number of occurrences is to be established using speculative parsing, and there are lower and upper bounds to control the speculation. The bounds are provided by the XSD minOccurs and XSD maxOccurs properties.

When parsing, up to maxOccurs occurrences are expected in the data. It is a Processing Error if less than XSD minOccurs occurrences are found or defaulted. The parser stops looking for occurrences when either XSD minOccurs have been found or defaulted and speculative parsing does not find another occurrence, or XSD maxOccurs have been found or defaulted. When XSD maxOccurs is 0, no occurrences are looked for in the data.

When unparsing, up to XSD maxOccurs occurrences are expected in the Infoset. It is a Processing Error if less than XSD minOccurs occurrences are found or defaulted. The processor stops looking for more occurrences in the Infoset after XSD maxOccurs occurrences have been found. When XSD maxOccurs is 0, no occurrences are looked for in the Infoset or written.

16.1.3 **ddfl:occursCountKind 'parsed'**

The enum 'parsed' should be used when the number of occurrences is to be established solely using speculative parsing.

When parsing, any number of occurrences is expected in the data. The parser stops looking for occurrences when speculative parsing does not find another occurrence. If validation is enabled, it is a Validation Error if less than XSD minOccurs occurrences are found or defaulted, or greater than XSD maxOccurs occurrences are found.

When unparsing, any number of occurrences is expected in the Infoset. If validation is enabled, it is a Validation Error if less than XSD minOccurs occurrences are found or defaulted, or if more than XSD maxOccurs occurrences are found.

16.1.4 **ddfl:occursCountKind 'expression'**

The enum 'expression' should be used when the number of occurrences is calculated by evaluating a DFDL expression.

When parsing, the dfdl:occursCount expression is evaluated and provides the number of occurrences expected in the data. It is a Processing Error if less than dfdl:occursCount occurrences are found or defaulted. The parser stops looking for occurrences when dfdl:occursCount occurrences have been found. If validation is enabled, it is a Validation Error if less than XSD minOccurs occurrences are found or defaulted, or more than XSD maxOccurs occurrences are found. When dfdl:occursCount is 0, no occurrences are looked for in the data.

When unparsing, any number of occurrences are expected in the Infoset. If validation is enabled, it is a Validation Error if less than XSD minOccurs occurrences are found or defaulted, or if more than XSD maxOccurs occurrences are found. The dfdl:occurs expression is not evaluated. The 'count' is the number of occurrences in the augmented Infoset.

It is a Schema Definition Error if dfdl:occursCount is not provided or in scope.

16.1.5 **ddfl:occursCountKind 'stopValue'**

The enum 'stopValue' should be used when the end of the array is signaled by an occurrence having a logical value that is equal to one of the specified 'stop values'.
When parsing, any number of occurrences is expected in the data, followed by an occurrence which is a stop value as specified by dfdl:occursStopValue. It is a Processing Error if a stop value occurrence is not found in the data (including when there are zero other occurrences). The parser stops looking for occurrences once a stop value has been found. If validation is enabled, it is a Validation Error if less than XSD minOccurs occurrences are found or defaulted, or more than XSD maxOccurs occurrences are found, not including the stop value.

When unparsing, the behavior is the same as for 'parsed', with the addition that a stop value occurrence is output after the last Infoset occurrence. If dfdl:occursStopValue provides multiple stop values then the first is used.

The stop value itself is **not** added to the Infoset when parsing. It is a Processing Error if a stop value is found in the Infoset when unparsing. (This ensures that the array can be re-parsed, as the stop value is placed automatically and only at the end.)

It is a Schema Definition Error if dfdl:occursStopValue is not provided or in scope.

It is a Schema Definition Error if the type of the element is complex.

It is a Schema Definition Error if any of the stop values provided by dfdl:occursStopValue do not conform to the simple type of the element.

### 16.2 Default Values for Arrays

When parsing, required occurrences that have empty representation may trigger the application of a default value, as described in Section 9.4.2 Element Defaults When Parsing.

When unparsing, required occurrences that are missing from the Infoset may trigger the application of a default value, as described in Section 9.4.3 Element Defaults When Unparsing.

The application of default values is **not** dependent on dfdl:occursCountKind, only on whether the occurrence is required or optional, whether there is a default value specified, and whether the data contains the empty representation (parsing) or is missing (unparsing). Section 9.4 Element Defaults contains the details.

### 16.3 Arrays with DFDL Expressions

If the value of a DFDL property of an array element (other than dfdl:occursCount) is given by a DFDL Expression, then the expression MUST be re-evaluated for each occurrence of the element in case the value changes.

### 16.4 Points of Uncertainty

Arrays can have points of uncertainty depending on the value of dfdl:occursCountKind. See Section 9.3.3 Resolving Points of Uncertainty for details.

### 16.5 Arrays and Sequences

In some situations, arrays of elements and sequence groups of elements seem to be similar; however, there is no notion of the array itself independent of its contained elements. Arrays are distinctly different from sequence groups in this way.

A sequence can have its own initiator, and a complex element having that sequence as its content can also have its own initiator, so one can express two different initiators.

Unlike a sequence group, an array does not have its own initiator, terminator, or alignment. Those properties apply to each element occurrence of the array. To give an alignment, initiator, separator, or terminator to an entire array one must enclose the element declaration for the array in a sequence group and specify the alignment, separator, initiator, and terminator on the sequence group.

### 16.6 Forward Progress Requirement

An array is potentially unbounded if any of the following are true:

- dfdl:occursCountKind is 'stopValue'
- dfdl:occursCountKind is 'parsed'
- dfdl:occursCountKind is 'implicit' and XSD maxOccurs is unbounded
To prevent an infinite loop, the parsing of an array that is potentially unbounded MUST terminate when the parsing of an occurrence makes no forward progress. This is detected when the following are true:

- The occurrence is a point of uncertainty;
- The position in the data does not move during the parsing of the occurrence (including any associated Separator, PrefixSeparator or PostfixSeparator region);
- The occurrence is known-to-exist with empty representation or nil representation.

In this situation, no forward progress occurs, and no way of ever detecting the end of the array is possible.

Upon termination of the array, any Infoset items already added to the array are retained except when dfdl:occursCountKind is 'stopValue' in which case this results in a Processing Error because the stop value will never be encountered.

Further, to prevent unnecessary consumption of resources for large bounded values of XSD maxOccurs, the parsing of an array must similarly terminate when the following are true:

- dfdl:occursCountKind is 'implicit';
- The occurrence is a point of uncertainty;
- The position in the data does not move during the parsing of the occurrence (including any associated Separator, PrefixSeparator, or PostfixSeparator region);
- The occurrence is known to exist with empty representation.

In this situation no forward progress occurs, and nothing is being added to the Infoset. Note that this differs from the above array termination because nil representation does not cause detection of this lack of forward progress as nilled element items are added to the Infoset, and the array eventually terminates when it contains XSD maxOccurs occurrences.

### 16.7 Parsing Occurrences with Non-Normal Representation

When parsing a single array, it is possible to extract occurrences that have different representations (nil, empty, normal, absent) although with some values of dfdl:lengthKind certain combinations of representations are not possible.

Occurrences with nil representation are added to the Infoset with [nilled] member true.

Occurrences with empty representation may or may not be added to the Infoset, as described in Section 9.4. If a required occurrence is not added to the Infoset, it may be a Processing Error, dependent on dfdl:occursCountKind as described in Section 16.1.

Occurrences with absent representation are not added to the Infoset. For a required occurrence it may be a Processing Error, dependent on dfdl:occursCountKind as described in Section 16.1.

### 16.8 Sparse Arrays

Consider parsing an array where optional occurrences with empty representation are present in the data, but there are also later optional occurrences present with normal representation. Such an array is called a 'sparse array'.

If the indices of the occurrences are significant and need to be preserved, then the array may be modelled using an element with XSD nillable 'true', dfdl:nilKind 'literalValue', dfdl:nilValue '%ES;' and dfdl:nilValueDelimiterPolicy the same as dfdl:emptyValueDelimiterPolicy. The occurrences with empty representation now become occurrences with nil representation, and produce nil values in the Infoset, so the absolute positions of all occurrences are preserved.

If the indices of the occurrences are not significant, then the array should be modelled using an element with XSD nillable 'false'. Optional occurrences with empty representation do not create items in the Infoset, so the absolute positions of any optional occurrences with normal representation are not preserved. Optional occurrences with empty representation are therefore skipped.
17 Calculated Value Properties

This section describes properties which allow the creation of calculated elements. When parsing, the value of a calculated element is derived using a DFDL Expression, and not by processing bytes from the data stream. When unparsing, the value of a calculated element is derived using a DFDL Expression and is not obtained from the Infoset in the usual way.

Calculated elements allow a technique that is commonly called layering. In this technique, some elements are said to be in the physical layer, and some in the logical layer. When parsing, the logical layer values are computed from physical layer values. When unparsing the opposite occurs, that is the physical layer values are computed from the logical layer values.

Calculated elements are commonly used with hidden elements to hide the physical layer elements so that they do not become part of the Infoset.

When a DFDL Schema is used to both parse and unp parse data, then a calculated element on parsing normally implies use of one or more calculated elements on unparsing.

These properties apply to elements of simple type.

</table>

dfdl-wg@ogf.org
An expression that calculates the value of the current element when unparsing.
The element must not be optional nor an array nor be global.
It is a Schema Definition Error if the result type of the expression does not conform to the base type of the element.
The value created using dfdl:outputValueCalc is validated like any other element value (when validation is enabled).
The value for the element, if any, in the Infoset is ignored.
The DFDL expression must not refer to this element nor cause a circular reference to this element. The expression may contain forward references to elements which have not yet been processed.
It is a Schema Definition Error if dfdl:outputValueCalc is specified on an element which has an XSD fixed or default property.
It is a Schema Definition Error if dfdl:inputValueCalc and dfdl:outputValueCalc are specified on the same element.
It is not possible to place this property in scope on a dfdl:format annotation.

Annotation: dfdl:element

Table 53 Calculated Value Properties

17.1 Example: 2d Nested Array
Consider this simple example. The data stream contains two elements giving the number of rows and number of columns of an array of numbers. The representation of the array is stored after these two elements.

```xml
<xs:complexType name="array">
  <xs:sequence dfdl:initiator="" >
    <xs:sequence dfdl:hiddenGroupRef="tns:hiddenArrayCounts"/>

    <xs:element name="rows" maxOccurs="unbounded" dfdl:occursCountKind="expression" dfdl:occursCount="{ ../nrows }">
      <xs:complexType>
        <xs:sequence>
          <xs:element name="cols" type="xs:float" maxOccurs="unbounded" dfdl:occursCountKind="expression" dfdl:occursCount=" { ../../ncols } " />
        </xs:sequence>
      </xs:complexType>
    </xs:element>
  </xs:sequence>
</xs:complexType>

<xs:group name="hiddenArrayCounts" >
  <xs:sequence>
    <xs:element name="nrows" type="xs:unsignedInt" dfdl:representation="binary" dfdl:lengthKind="implicit" dfdl:outputValueCalc="{ count(../rows) }"/>
    <xs:element name="ncols" type="xs:unsignedInt" dfdl:representation="binary" dfdl:lengthKind="implicit" dfdl:outputValueCalc=" ">{ if ( count(../rows) ge 1 ) then count(../rows[1]/cols) else }
  </xs:sequence>
</xs:complexType>
```

An expression that calculates the value of the current element when unparsing.
The element must not be optional nor an array nor be global.
It is a Schema Definition Error if the result type of the expression does not conform to the base type of the element.
The value created using dfdl:outputValueCalc is validated like any other element value (when validation is enabled).
The value for the element, if any, in the Infoset is ignored.
The DFDL expression must not refer to this element nor cause a circular reference to this element. The expression may contain forward references to elements which have not yet been processed.
It is a Schema Definition Error if dfdl:outputValueCalc is specified on an element which has an XSD fixed or default property.
It is a Schema Definition Error if dfdl:inputValueCalc and dfdl:outputValueCalc are specified on the same element.
It is not possible to place this property in scope on a dfdl:format annotation.

Annotation: dfdl:element

Table 53 Calculated Value Properties

17.1 Example: 2d Nested Array
Consider this simple example. The data stream contains two elements giving the number of rows and number of columns of an array of numbers. The representation of the array is stored after these two elements.
In the example above there are two hidden elements named 'nrows' and 'ncols'. These hidden elements' values are computed when unparsing from the number of occurrences in the 'rows' and 'cols' repeating elements. The 'rows' and 'cols' repeating elements number of occurrences are computed when parsing from the hidden elements 'nrows' and 'ncols'.

### 17.2 Example: Three-Byte Date

Logically, the data is a date.

```
<xs:element name="d" type="date"/>
```

Physically, it is stored as 3 single byte integers.

The format of this data is expressed as this schema:

```
<xs:sequence dfdl:representation="binary">
  <xs:element name="mm" type="byte" />
  <xs:element name="dd" type="byte" />
  <xs:element name="yy" type="byte"/>
</xs:sequence>
```

This physical representation can be hidden so that it does not become part of the Infoset:

```
<xs:sequence>
  <xs:sequence dfdl:hiddenGroupRef="tns:hiddenpDate"/>
  <xs:element name="d" type="date">
    ...
  </xs:element>
</xs:sequence>
```

A calculation can be used to compute the logical date element 'd' from the physical 'pdate' when parsing:

```
<xs:sequence>
  ... hidden pdate here ...
  <xs:element name="d" type="date">
    <xs:annotation>
      <xs:appinfo source="http://www.ogf.org/dfdl/">
        <dfdl:element>
          <dfdl:property name="inputValueCalc">
            { fn:date(fn:concat(if(../pdate/yy gt 50 )then "19" else "20", 
              if ( ../pdate/yy gt 9 )
              then xs:string(../pdate/yy)
              else fn:concat("0", 
                xs:string(../pdate/yy)), 
              "-", 
              xs:string(../pdate/mm)), 
          ...
        </xs:annotation>
      </xs:property>
    </xs:element>
  </xs:sequence>
```
The expression above assembles a string resembling, for example, "2005-12-17" or "1957-3-9" which is the string representation of a date that is acceptable to the `fn:date` constructor function. The hidden element 'pdate' is referenced by relative paths. The expression './/pdate/yy' accesses an element of type 'int', and the `xs:string` constructor function turns it into an integer.

Finally, one must handle the unparse case where the physical layer is computed from the logical layer:

```xml
<xs:sequence dfdl:representation="binary"
    <xs:element name="mm" type="byte"
        dfdl:outputValueCalc="{ fn:month-from-date(.//d) }" />
    <xs:element name="dd" type="byte"
        dfdl:outputValueCalc="{ fn:day-from-date(.//d) }" />
    <xs:element name="yy" type="byte"
        dfdl:outputValueCalc="{ fn:year-from-date(.//d) idivmod 100 }"/>
</xs:sequence>
```

The entire example in one place:

```xml
<xs:sequence>
    <xs:sequence dfdl:representation="binary"
        <xs:element name="mm" type="byte"
            dfdl:outputValueCalc="{ fn:month-from-date(.//d) }" />
        <xs:element name="dd" type="byte"
            dfdl:outputValueCalc="{ fn:day-from-date(.//d) }" />
        <xs:element name="yy" type="byte"
            dfdl:outputValueCalc="{ fn:year-from-date(.//d) idivmod 100 }"/>
    </xs:sequence>
</xs:sequence>
```
The above sequence contains logically only a single date element.
### 18 DFDL Expression Language

The DFDL expression language allows the processing of values conforming to the data model defined in the DFDL Infoset. It allows properties in the DFDL schema to be dependent on the value of an occurrence of an element or the value of a DFDL variable. For example, the length of the content of an element can be made dependent on the value of another element in the document.

The main uses of the expression language are as follows:

1. **When a DFDL property needs to be set dynamically at parse time from the value of one or more elements of the data.** Properties such as `dfdl:initiator`, `dfdl:terminator`, `dfdl:length`, `dfdl:occursCount`, and `dfdl:separator` accept an expression.

2. **In a `dfdl:assert` annotation**

3. **In a `dfdl:discriminator` annotation to resolve uncertainty when parsing**

4. **In a `dfdl:inputValueCalc` property to derive the value of an element in the logical model that doesn't exist in the physical data.**

5. **In a `dfdl:outputValueCalc` property to compute the value of an element on unparsing.**

6. **As the value in a `dfdl:setVariable` annotation or the `dfdl:defaultValue` in a `dfdl:defineVariable` or `dfdl:newVariableInstance`.

The DFDL expression language is a subset of XPath 2.0 [XPath]. DFDL uses a subset of XML schema and has a simpler information model, so only a subset of XPath 2.0 expressions is meaningful in DFDL Schemas. For example, there are no attributes in DFDL, so the attribute axis is not needed.

XPath 2.0 specification [XPATH2] allows implementation-dependent evaluation of expressions thereby allowing either lazy (sequential) evaluation or full (parallel) evaluation of expressions with OR and AND clauses. This flexibility is not desirable in DFDL 1.0 implementations, so the specification is changed to prescribe lazy (sequential) evaluation left-to-right.

In addition, DFDL expressions never return node-sequences having more than one node. DFDL expressions either return a simple value, a node sequence containing exactly one node/value, or an empty node sequence. Node sequences of length greater than one can be used within the expression, just not as the final result. Alternatively, one can state this as there are no constructs in DFDL which can accept a node sequence of more than one node; hence, DFDL expressions can never return a node sequence of more than one node as their final result.

For nilled elements, an attempt to get the value of a nilled element returns an empty node sequence.

DFDL implementations MUST comply with the error code behaviour in Appendix G of the XPath 2.0 spec and map these to the correct DFDL failure type. All but one of XPath's errors map to a Schema Definition Error. The exception is XPTY0004, which is used both for static and dynamic cases of type mismatch. A static type mismatch maps to a Schema Definition Error, whereas a dynamic type mismatch maps to a Processing Error. A DFDL implementation SHOULD distinguish the two kinds of XPTY0004 error if it is able to do so, but if unable it MUST map all XPTY0004 errors to a Schema Definition Error.

Implementation Note: DFDL implementations MAY use off-the-shelf XPath 2.0 processors, but must pre-process DFDL expressions to ensure that the behaviour matches the DFDL specification:

- Ensure that what is returned as the result is not a sequence with length > 1 by appropriate use of `fn:exactly-one()`.
- Check for the disallowed use of those XPath 2.0 functions that are not in the DFDL subset

XPath 2.0 specification [XPATH2] defines its functions to be in namespace http://www.w3.org/2005/xpath-functions. The DFDL specification assumes namespace prefix “fn:” is bound to this namespace.
18.1 Expression Language Data Model
The DFDL expression language operates on the DFDL augmented Infoset with the addition of the hidden elements.

Relative path expressions are evaluated relative to the current Infoset Element Information Item, also referred to as the current element for short.

In general, a DFDL expression can only reference an element that precedes the position in the schema where the expression is declared, and it is a schema definition otherwise, with the following exceptions:

- An assert or discriminator on a component may reference an element that is a descendent of the component.
- A dfdl:outputValueCalc property may reference an element that follows the position in the schema where the property is specified.

Implementations MAY have implementation-defined limitations on the use of forward or backward reference or MAY provide controls for bounding the reach of such references. These mechanisms are beyond the scope of this specification.

18.2 Variables
A variable is a binding between a (qualified) name and a (typed) value. Variables are defined using the dfdl:defineVariable annotation (see 7.7); defining a variable causes an initial instance also to be created. Further instances of variables are created using the dfdl:newVariableInstance annotation. Instances of variables are assigned a value using the dfdl:setVariable annotation. Variables are referenced in expressions by preceding the QName with '$'.

This section describes the semantics of variables. Any implementation consistent with the behavior described here is acceptable.

The memory where the information about a variable is stored during DFDL processing is called the variable memory. A variable is a name that is associated with a storage tuple in the variable memory.

Specifically, the variable memory contains:

- a counter used to generate locations for new tuples. Initial value is 1.
- an ordered list of locations. Each location contains a tuple of values:
  - has Been-set flag. This Boolean is originally false. dfdl:setVariable changes this flag to true.
  - has Been-referenced flag. This Boolean is originally false. Evaluation of an expression that uses the variable value changes the value to true.
  - has Value flag. This Boolean is originally true if the dfdl:defineVariable or dfdl:newVariableInstance annotation has a default value specified, or if a default value has been supplied externally. Otherwise it is false but is set to true if a dfdl:setVariable annotation is processed.
  - typeID. This string is a type identifier taken from the type specified in the dfdl:defineVariable annotation.
  - value. This is a typed value, or the distinguished value "unknown". The type of the value MUST correspond to the typeID. The value is optionally specified in dfdl:defineVariable or dfdl:newVariableInstance annotations in which case it is referred to as the default value for the variable. A default value may also be provided by the DFDL processor when the variable is defined with external "true".

The variable memory is initialized when a dfdl:defineVariable annotation is encountered. Each time a dfdl:newVariableInstance annotation is encountered, the parser captures the current value of the counter from the variable memory. It then creates a new variable memory where the location counter's value is one greater, and where the list of locations has been augmented with a new tuple at the location given by the prior value of the location counter. The tuple is initialized based on the specifics of the dfdl:defineVariable annotation.
18.2.1 Rewinding of Variable Memory State

Upon exit of the scope where the new variable instance was created, the newly created variable memory is discarded, and the prior variable memory is restored.

Note that the above algorithm ensures that each time a dfdl:newVariableInstance is encountered, a fresh location is initialized for it, and once the scope containing that variable goes out of scope, the instance tuple for the variable can no longer be reached. A different variable instance tuple is then visible.

18.2.2 Variable Memory State Transitions

The flags in the variable memory tuples are interpreted and modified as follows:

<table>
<thead>
<tr>
<th>DFDL annotation</th>
<th>before annotation processed</th>
<th>after annotation processed</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>has-been-set</td>
<td>has-been-referenced</td>

<td>false</td>
<td>false</td>
</tr>
<tr>
<td></td>
<td>false</td>
<td>false</td>
</tr>
<tr>
<td></td>
<td>false</td>
<td>true</td>
</tr>
<tr>
<td></td>
<td>true</td>
<td>any</td>
</tr>
<tr>
<td>reference variable (from DFDL expression)</td>
<td>tuple doesn’t exist</td>
<td>false</td>
</tr>
<tr>
<td></td>
<td>false</td>
<td>false</td>
</tr>
<tr>
<td></td>
<td>any</td>
<td>any</td>
</tr>
</tbody>
</table>

Table 54 Memory States for Expression Language Variables

The above table describes a set of rules which might be abbreviated as:

- write once, read many
- no write after the value has been read
An exception to this behavior occurs whenever the DFDL processor backtracks because it is processing multiple arms of a choice or as a result of speculative parsing. In this case the variable state is also rewound.

It is a Schema Definition Error if a dfdl:setVariable or a variable reference occurs and there is no corresponding variable name defined by a dfdl:defineVariable annotation.

It is a Schema Definition Error if a dfdl:setVariable provides a value of incorrect type which does not correspond to the type specified by the dfdl:defineVariable.

It is a Schema Definition Error if a variable reference in an expression is able to return a value of incorrect type for the evaluation of that expression. That is, DFDL - including the expressions contained in it - is a statically type-checkable language. DFDL implementations SHOULD issue these Schema Definition Errors prior to processing time if possible.

Even if the errors are detected at processing time, the errors associated with write-after-read, and double-write are Schema Definition Errors because they indicate the schema is not properly designed to use variables consistent with their single-assignment behavior.

18.3 General Syntax

DFDL expressions follow the XPath 2.0 syntax rules but are always enclosed in curly braces "{" and "}".

When a property accepts either a DFDL string literal or a DFDL expression, and the value is a string literal starting with a "{" character, then "{{{ must be used to escape the "{" character. Note that no escaping is required on the "}" character.

The syntax "{{" is a Schema Definition Error as it results in an empty XPath 2.0 expression which is not legal. It is not the equivalent of setting the property to empty string.

Examples

```
{ /book/title }
{ $x+2 }
{ if (fn:exists(../field1)) then 1 else 0 }
```

The result of evaluating the expression must be a single atomic value of the type expected by the context, and it is a Schema Definition Error otherwise. Some XPath expressions naturally return a sequence of values, and in this case, it is also Schema Definition Error if an expression returns a sequence containing more than one item.

Additionally:

- Every property that accepts an expression states exactly what the expression is expected to return. To ensure the returned value is of the correct type, an expression must use XPath constructors or the correct literal values.
- What appears lexically as the syntax of an expression follows XPath 2.0 rules. Note specifically that this is not the same as XSD default and XSD fixed property lexical syntax. Specifically, XSD default and XSD fixed properties do not accept expressions. They are always interpreted as XML Schema string literals. See [XSD] for details.
- No extra auto-casting is performed over and above that provided by XPath 2.0. XPath 2.0 has rules for when it promotes types and when it allows types to be substituted. These are in Appendix B.1 of the XPath 2.0 spec.
- If the property is not expecting an expression to return a DFDL string literal, the returned value is never treated as a DFDL string literal.
- If expecting an expression to return a DFDL string literal, the returned value is always treated as a DFDL string literal.
- Within an expression, a string is never interpreted as a DFDL string literal.

18.4 DFDL Expression Syntax

Refer to XML Path Language (XPath) 2.0 [XPath] for a description of XPath expressions

```
DFDL Expression ::= "{" Expr "}"
```
```
Expr    ::=    ExprSingle
ExprSingle ::=    IfExpr | OrExpr
IfExpr    ::=    "if" (" Expr ") "then" ExprSingle "else" ExprSingle
OrExpr    ::=    AndExpr ( "or" AndExpr )
AndExpr    ::=    ComparisonExpr ( "and" ComparisonExpr )
ComparisonExpr    ::=    AdditiveExpr ( (ValueComp ) AdditiveExpr)?
AdditiveExpr    ::=    MultiplicativeExpr ( ("+" | "-") MultiplicativeExpr )

Table 55 DFDL Expression Language

Notes:
1. Only $if$ and $path$ expression types are supported
2. Only the $child$, $parent$, and $self$ axes are supported
3. Predicates are only used to index arrays and so must be integer expressions otherwise a Schema Definition Error occurs
4. A subset of the XPath 2.0 operators is supported
5. NameTest - These QNames are path steps that refer to elements in the DFDL Infoset. If such an element is in a namespace, then the NameTest QName must have a prefix which is bound to the namespace. Specifically, any default namespace is not used to implicitly qualify these NameTest QNames. This behavior is consistent with XPath expression usage in XML Schema [Walmsley] such as in the path property of the xs:selector and xs:field elements within xs:key and xs:unique constraints, and in related XML standards such as XSLT. Note however, that this behavior is different from the way QNames are used in other places in XML and DFDL Schemas such as the ref property of an element reference, or the dfdl:ref property of a DFDL format annotation. There a QName with no prefix must always be referring to a global declaration or definition, and so is augmented with the default namespace when needed.

18.5 Constructors, Functions and Operators

In the function signatures below a '?' following an argument name, argument type or result type indicates that the argument/result can be a node or value of the expected type or it can have no value.

18.5.1 Constructor Functions for XML Schema Built-in Types

The arguments to the constructors are all of type xs:anyAtomicType. Since the expression language can be statically type checked, it is a Schema Definition Error if the type of the argument is not one of the DFDL-supported subtypes of xs:anyAtomicType, however, many statically type-correct values are still not convertible to the result type. It is a Processing Error if the supplied argument value is not convertible to the constructed type.

The following constructor functions for the built-in types are supported:

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>xs:string($arg as xs:anyAtomicType) as xs:string</td>
<td></td>
</tr>
<tr>
<td>xs:boolean($arg as xs:anyAtomicType) as xs:boolean</td>
<td></td>
</tr>
<tr>
<td>xs:decimal($arg as xs:anyAtomicType) as xs:decimal</td>
<td></td>
</tr>
<tr>
<td>xs:float($arg as xs:anyAtomicType) as xs:float</td>
<td></td>
</tr>
<tr>
<td>xs:double($arg as xs:anyAtomicType) as xs:double</td>
<td></td>
</tr>
<tr>
<td>xs:dateTime($arg as xs:anyAtomicType) as xs:dateTime</td>
<td></td>
</tr>
<tr>
<td>xs:time($arg as xs:anyAtomicType) as xs:time</td>
<td></td>
</tr>
<tr>
<td>xs:date($arg as xs:anyAtomicType) as xs:date</td>
<td></td>
</tr>
<tr>
<td>xs:hexBinary($arg as xs:anyAtomicType) as xs:hexBinary</td>
<td></td>
</tr>
<tr>
<td>xs:integer($arg as xs:anyAtomicType) as xs:integer</td>
<td></td>
</tr>
<tr>
<td>xs:long($arg as xs:anyAtomicType) as xs:long</td>
<td></td>
</tr>
</tbody>
</table>
Table 56 Basic Constructors
A special constructor function is provided for constructing a `xs:dateTime` value from an `xs:date` value and an `xs:time` value.

<table>
<thead>
<tr>
<th>Function</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>fn:dateTime($arg1 as xs:date, $arg2 as xs:time) as xs:dateTime</td>
<td>Constructs the <code>xs:dateTime</code> value.</td>
</tr>
</tbody>
</table>

Table 57 Special Constructor for `xs:dateTime`

18.5.2 Standard XPath Functions

18.5.2.1 Boolean functions
The following additional constructor functions are defined on the boolean type.

<table>
<thead>
<tr>
<th>Function</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>fn:true()</td>
<td>Constructs the <code>xs:boolean</code> value 'true'.</td>
</tr>
<tr>
<td>fn:false()</td>
<td>Constructs the <code>xs:boolean</code> value 'false'.</td>
</tr>
</tbody>
</table>

Table 58 Boolean functions
The following functions are defined on boolean values. The return type of these functions is `xs:boolean`.
Function | Meaning
--- | ---
fn:not($arg?) | If $arg$ is the empty sequence or a node with \[nilled\] true, \(\text{fn:not}\) returns true.
If $arg$ is a sequence containing a node with \[nilled\] false or \[nilled\] having no value (that is, a node corresponding to a non-nilable element), \(\text{fn:not}\) returns false.
If $arg$ is a value of type \(\text{xs:boolean}\) or a derived from \(\text{xs:boolean}\), \(\text{fn:not}\) returns the boolean inverse of $arg$.
If $arg$ is a value of type \(\text{xs:string}\) or a type derived from \(\text{xs:string}\), \(\text{fn:not}\) returns true if the operand value has zero length; otherwise it returns false.
If $arg$ is a value of any numeric type or a type derived from a numeric type, \(\text{fn:not}\) returns true if the operand value is NaN or is numerically equal to zero; otherwise it returns false.
In all other cases, \(\text{fn:not}\) raises a Processing Error.
Inverts the \(\text{xs:boolean}\) value of the argument.

### Table 59 Boolean functions

#### 18.5.2.2 Numeric Functions

The following functions are defined on numeric types. Each function returns a value of the same type as the type of its argument. The argument must be convertible to a number type.

<table>
<thead>
<tr>
<th>Function</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>fn:abs($arg as numeric)</td>
<td>Returns the absolute value of the argument.</td>
</tr>
<tr>
<td>fn:ceiling($arg as numeric)</td>
<td>Returns the smallest number with no fractional part that is greater than or equal to the argument.</td>
</tr>
<tr>
<td>fn:floor($arg as numeric)</td>
<td>Returns the largest number with no fractional part that is less than or equal to the argument.</td>
</tr>
<tr>
<td>fn:round($arg as numeric)</td>
<td>Rounds to the nearest number with no fractional part. When the value is x.5, it rounds toward positive infinity.</td>
</tr>
<tr>
<td>fn:round-half-to-even($arg as numeric)</td>
<td>Takes a number and a precision and returns a number rounded to the given precision. If the fractional part is exactly half, the result is the number whose least significant digit is even.</td>
</tr>
</tbody>
</table>

### Table 60 Numeric Functions

#### 18.5.2.3 String Functions

The following functions are defined on values of type \(\text{xs:string}\) and types derived from it. In the functions below which compare strings, DFDL always uses the default Unicode collation algorithm (which is a comparison of codepoint values).

<table>
<thead>
<tr>
<th>Function</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>fn:concat( $arg1 as \text{xs:anyAtomicType}, $arg2 as \text{xs:anyAtomicType}, ... )</td>
<td>Concatenates two or more \text{xs:anyAtomicType} arguments cast to \text{xs:string}.</td>
</tr>
</tbody>
</table>
fn:substring($sourceString as xs:string, $startingLoc as xs:double)
fn:substring($sourceString as xs:string, $startingLoc as xs:double, $length as xs:double)

Returns the xs:string located at a specified place within an argument xs:string.

fn:string-length($arg as xs:string)

Returns the length of the argument as an xs:integer

fn:upper-case($arg as xs:string)

Returns the upper-cased value of the argument.

fn:lower-case($arg as xs:string)

Returns the lower-cased value of the argument.

fn:contains($arg1 as xs:string, $arg2 as xs:string)

Returns xs:boolean indicating whether one xs:string contains another xs:string.

fn:starts-with($arg1 as xs:string, $arg2 as xs:string)

Returns xs:boolean indicating whether the value of one xs:string begins with the characters of another xs:string.

fn:ends-with($arg1 as xs:string, $arg2 as xs:string)

Returns xs:boolean indicating whether the value of one xs:string ends with the characters of another xs:string.

fn:substring-before($arg1 as xs:string, $arg2 as xs:string)

Returns the characters of one xs:string that precede in that xs:string the characters of another xs:string.

fn:substring-after($arg1 as xs:string, $arg2 as xs:string)

Returns the characters of xs:string that follow in that xs:string the characters of another xs:string.

### Table 61 String Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>fn:year-from-dateTime($arg as xs:dateTime)</td>
<td>Returns the year from an xs:dateTime value as an xs:integer.</td>
</tr>
<tr>
<td>fn:month-from-dateTime($arg as xs:dateTime)</td>
<td>Returns the month from an xs:dateTime value as an xs:integer.</td>
</tr>
<tr>
<td>fn:day-from-dateTime($arg as xs:dateTime)</td>
<td>Returns the day from an xs:dateTime value as an xs:integer.</td>
</tr>
<tr>
<td>fn:hours-from-dateTime($arg as xs:dateTime)</td>
<td>Returns the hours from an xs:dateTime value as an xs:integer.</td>
</tr>
<tr>
<td>fn:minutes-from-dateTime($arg as xs:dateTime)</td>
<td>Returns the minutes from an xs:dateTime value as an xs:integer.</td>
</tr>
<tr>
<td>fn:seconds-from-dateTime($arg as xs:dateTime)</td>
<td>Returns the seconds from an xs:dateTime value as an xs:decimal.</td>
</tr>
<tr>
<td>fn:year-from-date($arg as xs:date)</td>
<td>Returns the year from an xs:date value as an xs:integer.</td>
</tr>
<tr>
<td>fn:month-from-date($arg as xs:date)</td>
<td>Returns the month from an xs:date value as an xs:integer.</td>
</tr>
<tr>
<td>Function</td>
<td>Meaning</td>
</tr>
<tr>
<td>-----------------</td>
<td>---------</td>
</tr>
<tr>
<td>fn:day-from-date($arg as xs:date)</td>
<td>Returns the day from an xs:date value as an xs:integer.</td>
</tr>
<tr>
<td>fn:hours-from-time($arg as xs:time)</td>
<td>Returns the hours from an xs:time value as an xs:integer.</td>
</tr>
<tr>
<td>fn:minutes-from-time($arg as xs:time)</td>
<td>Returns the minutes from an xs:time value as an xs:integer.</td>
</tr>
<tr>
<td>fn:seconds-from-time($arg as xs:time)</td>
<td>Returns the seconds from an xs:time value as an xs:decimal.</td>
</tr>
</tbody>
</table>

### Table 62 Date and Time Functions

#### 18.5.2.5 Node Sequence Test Functions

The following functions are defined on sequences. (Note that DFDL v1.0 does not support sequences of length > 1 as the final results of expressions.)

In the functions below, if the argument includes the current node, or any enclosing parent node, then it is a Schema Definition Error.

<table>
<thead>
<tr>
<th>Function</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>fn:empty($arg?)</td>
<td>Indicates whether the provided sequence is empty.</td>
</tr>
<tr>
<td>fn:exists($arg?)</td>
<td>Indicates whether the provided sequence is not empty.</td>
</tr>
<tr>
<td>fn:exactly-one($arg?)</td>
<td>Returns the input sequence if it contains exactly one item. Raises an error otherwise.</td>
</tr>
<tr>
<td>fn:count($arg)</td>
<td>Returns the number of items in the value of $arg as an xs:integer. Returns 0 if $arg is the empty sequence.</td>
</tr>
</tbody>
</table>

### Table 63 Node Sequence Test Functions

#### 18.5.2.6 Node functions

This section discusses functions and operators on nodes.

<table>
<thead>
<tr>
<th>Function</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>fn:local-name()</td>
<td>Returns the local name of the context node as an xs:string.</td>
</tr>
<tr>
<td>fn:local-name($arg)</td>
<td>Returns the local name of the specified node as an xs:string.</td>
</tr>
<tr>
<td>fn:namespace-uri()</td>
<td>Returns the namespace URI as an xs:string for the argument node or the context node if the argument is omitted. Returns empty string if the argument/context node is in no namespace.</td>
</tr>
</tbody>
</table>

### Table 64 Node functions

#### 18.5.2.7 Nillable Element Functions

This section discusses functions related to nillable elements.

<table>
<thead>
<tr>
<th>Function</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>fn:nilled($arg?)</td>
<td>Returns an xs:boolean true when the argument node Infoset member [nilled] is true and false when [nilled] is false. If the argument is not an element node, returns the empty sequence. If the argument is the empty sequence, returns the empty sequence. If the argument is an element node and [nilled] has no value returns the empty sequence.</td>
</tr>
</tbody>
</table>

### Table 65 Nillable Element Functions
## 18.5.3 DFDL Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>dfdl:contentLength($node, $lengthUnits)</td>
<td>Returns the length of the supplied node's SimpleContent region for elements of simple type, or ComplexContent region for elements of complex type. These regions are defined in Section 9.2 DFDL Data Syntax Grammar. The value is returned as an xs:unsignedLong. The second argument is of type xs:string and must be 'bytes', 'characters', or 'bits' (Schema Definition Error otherwise) and determines the units of length.</td>
</tr>
<tr>
<td>dfdl:valueLength($node, $lengthUnits)</td>
<td>Returns the length of the supplied node's SimpleLogicalValue region for elements of simple type, or ComplexValue region for elements of complex type. These regions are defined in Section 9.2 DFDL Data Syntax Grammar. The value is returned as an xs:unsignedLong. For simple types, the dfdl:valueLength() function returns a length which excludes any padding or filling. The second argument is of type xs:string and must be 'bytes', 'characters', or 'bits' (Schema Definition Error otherwise) and determines the units of length.</td>
</tr>
<tr>
<td>dfdl:testBit($data, $bitPos)</td>
<td>Returns Boolean true if the bit number given by the xs:nonNegativeInteger $bitPos is set on in the xs:unsignedByte given by $data, otherwise returns Boolean false.</td>
</tr>
<tr>
<td>dfdl:setBits($bit1, $bit2, ... $bit8)</td>
<td>Returns an unsigned byte being the value of the bit positions provided by the Boolean arguments, where true is 1, false is 0. The number of arguments must be 8.</td>
</tr>
<tr>
<td>dfdl:occursIndex()</td>
<td>Returns the position of the current item of an array as an xs:nonNegativeInteger. The first element is at position 1. The function may be used on non-array elements so long as it appears within the dynamic scope of some array element. In this case it returns the index of the current item of the innermost enclosing array element. It is a Schema Definition Error if this function is called when there is no enclosing array element.</td>
</tr>
<tr>
<td>dfdl:checkConstraints($node)</td>
<td>Returns boolean true if the specified node value satisfies the XML schema facet constraints that are associated with it. Returns false if the specified node does not meet the constraints or does not exist. The facets that are checked are - minLength, maxLength - pattern</td>
</tr>
</tbody>
</table>
- enumeration
- maxInclusive, maxExclusive, minExclusive, minInclusive
- totalDigits
- fractionDigits

See Section 5.3 for which facets are checked for each simple type.
Additionally, the XSD fixed property is checked.
It is a Schema Definition Error if the argument is a complex element.

dfdl:encodeDFDLEntities($arg)
Returns a string containing a DFDL string literal constructed from the $arg string argument. If $arg contains any '%' and/or space characters, then the return value replaces each '%' with '%%' and each space with '%SP;', otherwise $arg is returned unchanged.

dfdl:decodeDFDLEntities ($arg)
Returns a string constructed from the $arg string argument. If $arg contains syntax matching DFDL Character Entities syntax, the corresponding characters are used in the result. Any characters in $arg not matching the DFDL Character Entities syntax remain unchanged in the result.
It is a Schema Definition Error if $arg contains syntax matching DFDL Byte Value Entities syntax.

dfdl:containsDFDLEntities($arg)
Returns a Boolean indicating whether the $arg string argument contains one or more DFDL entities.

dfdl:timeZoneFromDateTime($arg)
dfdl:timeZoneFromDate($arg)
dfdl:timeZoneFromTime ($arg)
Returns the timezone component, if any, of $arg as an xs:string. The $arg is of type xs:dateTime, xs:date and xs:time respectively.
If $arg has a timezone component, then the result is a string in the format of an ISO Time zone designator. Interpreted as an offset from UTC, its value may range from +14:00 to -14:00 hours, both inclusive. The UTC time zone is represented as "+00:00". If the $arg has no timezone component, then "" (empty string) is returned.

dfdl:checkRangeInclusive($node, $val1, $val2)
dfdl:checkRangeExclusive($node, $val1, $val2)
Returns boolean true if the specified node value is in the range given by $val1 and $val2.
The type of $val1 and $val2 must be compatible with the type of $node, and must be a derivative of xs:decimal, xs:float or xs:double. It is a Schema Definition Error if the $node argument is a complex element.

Table 66 DFDL Functions

Notes:
dfdl:valueLength(path, lengthUnits) - returns the value length which excludes any padding or filling which might be added for a specified length.
If the element declaration in the DFDL schema corresponding to the Infoset item has the 
dfdl:inputValueCalc property, then the unpadded length is defined to be 0.
The value length includes the length contributions from introduced escape characters needed to 
escape contained delimiters (if such are defined and would appear in the output representation).
The value length is also a function of the dfdl:encoding property. Multi-byte and variable-width 
character set encodings commonly contribute more bytes to the value length than a single-byte 
character set would.
The value length is computed from the DFDL Infoset value, ignoring the dfdl:length or 
dfdl:textOutputMinLength property. Other DFDL properties which affect the length of a text or 
binary representation are respected, it is only an explicit length which is ignored.
For a complex type, this means a bottom up totaling of the dfdl:contentLength() of all the contents 
and framing of the complex type.
dfdl:contentLength(path, lengthUnits) – returns the length of the content of the Infoset data item 
as identified by the path argument. This includes padding or filling or truncation which might be 
carried out for a specified length item.
If the element declaration in the DFDL schema corresponding to the Infoset item has a 
dfdl:inputValueCalc property, then the length is defined to be 0.
When unparsing with dfdl:lengthKind "explicit", the calculation of dfdl:contentLength() returns the 
value of the dfdl:length property.
For both dfdl:contentLength() and dfdl:valueLength(), the content length excludes any alignment 
filling as well as excluding any leading or trailing skip bytes. That is, the returned length is about 
the length of the content, and not about the position of that content in the output data stream.
Use dfdl:encodeDFDLEntities() when the value of a DFDL property is obtained from the data 
stream using an expression, and the type of the property is DFDL String Literal or List of DFDL 
String Literals, and the values extracted from the data stream can contain '%' or space characters. If the data already contains DFDL entities, this function should not be used.
The dfdl:decodeDFDLEntities() function is used to create a value which contains characters for 
which DFDL Character Entities are needed. An example is to create data containing the NUL 
(character code 0) codepoint. This character code is not allowed in XML documents, including 
DFDL Schemas; hence, it must be specified using a DFDL Character Entity. Within a DFDL 
Expression, use this function to obtain a string containing this character.

18.5.4 DFDL Constructor Functions
There is sometimes a need to create a number type from hex binary, and a hex binary type from 
a number. Accordingly, the following new DFDL specific functions are provided.

<table>
<thead>
<tr>
<th>Function</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>dfdl:byte ($arg)</td>
<td>These constructor functions behave identically to the XPath 2.0 constructor functions of the same names, with one exception. The argument can be a quoted string beginning with the letter 'x', in which case the remainder of the string is hexadecimal digits that represent a big-endian twos complement representation of a binary number.</td>
</tr>
<tr>
<td>dfdl:unsignedByte ($arg)</td>
<td>If the string begins with 'x', it is a Schema Definition Error if a character appears other 0-9, a-f, A-F.</td>
</tr>
<tr>
<td>dfdl:short ($arg)</td>
<td>Each constructor function has a limit on the number of hex digits, with no more digits than 2, 4, 8, or 16 for the byte, short, int and long versions respectively. It is a Schema Definition Error if more digits are encountered than are suitable for the type being created</td>
</tr>
</tbody>
</table>
This constructor function behaves identically to the XPath 2.0 constructor function of the same name, with one exception. The argument can also be a long, unsignedLong, or any subtype thereof, and in that case a xs:hexBinary value containing a number of hex digits is produced. The ordering and number of the digits correspond to a binary big-endian two's-complement implementation of the type of the argument. Digits 0-9, A-F are used.

The number of digits produced depends on the type of $arg, being 2, 4, 8 or 16. If $arg is a literal number then the type is the smallest signed type (long, int, short, byte) that can contain the value.

If a literal number is not able to be represented by a long, it is a Schema Definition Error.

### Table 67: DFDL Constructor Functions

Examples:
- `dfdl:unsignedInt("xa1b2c3d4")` is the unsigned int value 2712847316.
- `dfdl:int("FFFFFFFF")` is the signed int value -1.
- `dfdl:unsignedByte("xFF")` is the unsigned byte value 255.
- `dfdl:byte("xff")` is the signed byte value -1.
- `dfdl:byte("xF7F")` is the signed byte value 127.
- `dfdl:byte("x80")` is the signed byte value -128.
- `dfdl:unsignedByte("x80")` is the unsigned byte value 128.
- `dfdl:byte("x0A3")` is a Schema Definition Error (too many digits for type).
- `dfdl:byte("xG3")` is a Schema Definition Error (invalid digit).
- `dfdl:hexBinary(xs:unsignedByte(208))` is the hexBinary value "D0".
- `dfdl:hexBinary(208)` is the hexBinary value "00D0".
- `dfdl:hexBinary(-2084)` is the hexBinary value "F7DC".

### 18.5.5 Miscellaneous Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>fn:error()</code></td>
<td>Causes a Processing Error. This function does not return a value. A Processing Error ends the evaluation of the expression.</td>
</tr>
<tr>
<td><code>fn:error($id as xs:string)</code></td>
<td>The $id argument is an error code identifier string that distinguishes this error from others. The string should have the structure of an XSD QName; the namespace URI conventionally identifies the component, subsystem, or authority responsible for defining the meaning of the error code, while the local part identifies the specific error condition. This information is incorporated into any diagnostic messages created by the DFDL implementation in response to the Processing Error in an implementation-dependent manner. If the $id argument string does not have the form of an XSD QName, or the QName cannot be interpreted as a meaningful namespace prefix and local identifier, then the Processing Error still occurs but the diagnostic message is created in an implementation-dependent manner.</td>
</tr>
<tr>
<td><code>fn:error($id as xs:string, $desc as xs:string, $obj?)</code></td>
<td></td>
</tr>
</tbody>
</table>
18.6 Unparsing and Circular Expression Deadlock Errors

It is possible for expressions and lengths of elements in a DFDL schema to interact badly, resulting in circular deadlocks. In these cases, an expression is unable to evaluate because it depends in some way on the length of something that depends on the expression itself. Expression deadlocks are always Schema Definition Errors.

One scenario where such a deadlock can arise is due to what is called the interior-alignment problem. In this scenario a dfdl:outputValueCalc expression depends on the dfdl:valueLength function being evaluated for a following complex element which due to interior alignments, has a length that depends on its starting position. In this case, a circular deadlock occurs, which is a unparse-time Processing Error.
19 DFDL Regular Expressions

A DFDL regular expression may be specified for the dfdl:lengthPattern format property and the dfdl:testPattern property of the dfdl:assert and dfdl:discriminator annotations. DFDL regular expressions do not interpret DFDL entities.

A DFDL regular expression is defined by a set of valid pattern characters. For portability, a DFDL regular expression pattern is restricted to the inclusive subset of the ICU regular expression [ICURegex] and the Java(R) 7 regular expression [JavaRegex] with the Unicode flags UNICODE_CASE and UNICODE_CHARACTER_CLASS turned on. DFDL regular expressions thereby conform to Unicode Technical Standard #18, Unicode Regular Expressions, level 1 [UnicodeRegex].

The following regular expression constructs are not common to both ICU and Java(R) 7 and it is a Schema Definition Error if any are used in a DFDL regular expression:

<table>
<thead>
<tr>
<th>Construct</th>
<th>Meaning</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>\n(UNICODE CHARACTER NAME)</td>
<td>Match the named character</td>
<td>ICU only</td>
</tr>
<tr>
<td>\X</td>
<td>Match a Grapheme Cluster</td>
<td>ICU only</td>
</tr>
<tr>
<td>\Uhhhhhhhh</td>
<td>Match the character with the hex value hhhhhhhh</td>
<td>ICU only</td>
</tr>
<tr>
<td>(?# ... )</td>
<td>Free-format comment</td>
<td>ICU only</td>
</tr>
<tr>
<td>(?w-w)</td>
<td>UREGEX_UWORD - Controls the behaviour of \b in a pattern</td>
<td>ICU only</td>
</tr>
<tr>
<td>(?d-d)</td>
<td>UNIX_LINES - Enables Unix lines mode</td>
<td>Java 7 only</td>
</tr>
<tr>
<td>(?u-u)</td>
<td>UNICODE_CASE - Enables Unicode-aware case folding</td>
<td>Java 7 only (1)</td>
</tr>
<tr>
<td>(?U-U)</td>
<td>UNICODE_CHARACTER_CLASS - Enables the Unicode version of predefined character classes and POSIX character classes</td>
<td>Java 7 only (2)</td>
</tr>
</tbody>
</table>

Table 68 Disallowed Regular Expression Constructs

Notes:
1. Implementations using Java 7 MUST set flag UNICODE_CASE by default to match ICU.
2. Implementations using Java 7 MUST set flag UNICODE_CHARACTER_CLASS by default to match ICU.

Additionally, the behaviour of the word character construct (\w) is not consistent in ICU and Java 7. In Java 7 \w is

`[^p{Alpha}|p{gc=Mn}|p{gc=Me}|p{gc=Mc}|p{Digit}|p{gc=Pc}]`,

which is a larger set than ICU where \w is

`[^p{Ll}|p{Lu}|p{Lt}|p{Lo}|p{Nd}]`.

The use of \w is not recommended in DFDL regular expressions in conjunction with Unicode encodings, and an implementation MUST issue a warning if such usage is detected.

Character properties are detailed by the Unicode Regular Expressions [UnicodeRegex].
20 External Control of the DFDL Processor

In addition to providing the DFDL schema and data to be parsed or serialized, DFDL Schemas can also be parameterized by external variables.

DFDL processors can provide implementation-defined means to specify:

1. The data to be processed: a data stream when parsing or an Infoset when unparsing.
2. The DFDL schema to be used.
3. The *distinguished global element declaration* to be used (specifying both name of element and namespace of that name)
4. Values for external variables

Notice also that a DFDL Schema, like any XML schema, can have multiple top-level element declarations; hence, the distinguished global element declaration is necessary to indicate which of these top-level element declarations is to be the starting point for processing data.

The mechanism by which a DFDL processor is controlled is not specified by this standard. For example, command line DFDL processors MAY use command line options, but DFDL processors embedded in other kinds of software systems may need other mechanisms.
21 Built-in Specifications

For convenience, a standard set of named DFDL format definitions MAY be provided with DFDL processors by implementations. These built-in format definitions may be imported by DFDL schema authors.
22 Conformance

DFDL conformance can be claimed for schema documents and for processors

A schema document conforms to this specification if it conforms to the subset of XML Schema 1.0 defined in Section 5.2 DFDL Subset of XML Schema and consists of components which individually and collectively satisfy all the relevant constraints specified in this document.

Conformance may be claimed separately for a DFDL parser, a DFDL unparser or a DFDL processor that parses and unparses.

1. A DFDL processor claiming conformance MUST identify the level of conformance and version specification claimed.
2. A minimal conforming DFDL processor conforms to this specification when it implements all the non-optional features defined in this document.
3. An extended conforming DFDL processor conforms to the specification when it implements all the non-optional features and some of the optional features defined in this document.
4. A fully conforming DFDL processor conforms to the specification when it implements all the features defined in this document.

See Section 23 Optional DFDL Features for the list of optional features

It is the intention of the DFDL Work Group to provide a conformance test suit to help verify conformance with this specification.
## 23 Optional DFDL Features

The following table lists the features of the DFDL language that are considered optional for DFDL processor implementations. This list admits very small subsets of the full DFDL specification. For example, a binary-only subset without any expressions or variables is specifically allowed.

<table>
<thead>
<tr>
<th>Feature</th>
<th>Detection</th>
</tr>
</thead>
<tbody>
<tr>
<td>Validation</td>
<td>External switch</td>
</tr>
<tr>
<td>Named Formats</td>
<td>dfdl:defineFormat or dfdl:ref</td>
</tr>
<tr>
<td>Choices</td>
<td>xs:choice in the schema</td>
</tr>
<tr>
<td>Arrays where size not known in advance</td>
<td>dfdl:occursCountKind 'implicit', 'parsed', 'stopValue'</td>
</tr>
<tr>
<td>Expressions</td>
<td>Use of a DFDL expression in any property value</td>
</tr>
<tr>
<td>End of parent</td>
<td>dfdl:lengthKind &quot;endOfParent&quot;</td>
</tr>
<tr>
<td>Simple type restrictions</td>
<td>xs:simpleType in the schema</td>
</tr>
<tr>
<td>Text representation for types other than String</td>
<td>dfdl:representation &quot;text&quot; for Number, Calendar or Boolean types</td>
</tr>
<tr>
<td>Delimiters</td>
<td>dfdl:separator &lt;&gt; &quot;&quot; or dfdl:initiator &lt;&gt; &quot;&quot; or dfdl:terminator &lt;&gt; &quot;&quot; or dfdl:lengthKind &quot;delimited&quot;</td>
</tr>
<tr>
<td>Nils</td>
<td>XSD nillable 'true' in the schema</td>
</tr>
<tr>
<td>Defaults</td>
<td>XSD default or XSD fixed in the schema</td>
</tr>
<tr>
<td>Defaulting to Empty String/Hex/Binary values in the Infoset</td>
<td>dfdl:emptyElementParsePolicy=&quot;treatAsEmpty&quot;</td>
</tr>
<tr>
<td>Lengths in Bits</td>
<td>dfdl:alignmentUnits 'bits' or dfdl:lengthUnits 'bits'</td>
</tr>
<tr>
<td>Delimited lengths and representation binary element</td>
<td>dfdl:representation 'binary' (or implied binary) and dfdl:lengthKind 'delimited'</td>
</tr>
<tr>
<td>Regular expressions</td>
<td>dfdl:lengthKind 'pattern', dfdl:assert with dfdl:testkind 'pattern', dfdl:discriminator with dfdl:testkind 'pattern'</td>
</tr>
<tr>
<td>Zoned numbers</td>
<td>dfdl:textNumberRep 'zoned'</td>
</tr>
<tr>
<td>IBM 390 packed numbers</td>
<td>dfdl:binaryNumberRep 'packed'</td>
</tr>
<tr>
<td>IBM 390 packed calendars</td>
<td>dfdl:binaryCalendarRep 'packed'</td>
</tr>
<tr>
<td>IBM 390 floats</td>
<td>dfdl:binaryFloatRep 'ibm390Hex'</td>
</tr>
<tr>
<td>Unordered sequences</td>
<td>dfdl:sequenceKind 'unordered'</td>
</tr>
<tr>
<td>Floating elements</td>
<td>dfdl:floating 'yes'</td>
</tr>
<tr>
<td>dfdl functions in expression language</td>
<td>DFDL functions in expression</td>
</tr>
<tr>
<td>Hidden groups</td>
<td>dfdl:hiddenGroupRef &lt;&gt; &quot;</td>
</tr>
<tr>
<td>Calculated values</td>
<td>dfdl:inputValueCalc &lt;&gt; &quot; or dfdl:outputValueCalc &lt;&gt; &quot;</td>
</tr>
<tr>
<td>Escape schemes</td>
<td>dfdl:defineEscapeScheme in the schema</td>
</tr>
<tr>
<td>Extended encodings</td>
<td>Any dfdl:encoding value beyond the core list</td>
</tr>
<tr>
<td>UTF-16 Variable Width Characters</td>
<td>dfdl:utf1 Width=&quot;variable&quot;</td>
</tr>
<tr>
<td>Asserts</td>
<td>dfdl:assert in the schema</td>
</tr>
</tbody>
</table>
Discriminators
  dfdl:discriminator in the schema

Prefixed lengths
  dfdl:lengthKind 'prefixed'

Variables
  dfdl:defineVariable,
  dfdl:newVariableInstances,
  dfdl:setVariable
  Variables in DFDL expression language
  Note that variables as a feature is dependent on the
  Expressions feature.

BCD calendars
  dfdl:binaryCalendarRep "bcd"

BCD numbers
  dfdl:binaryNumberRep "bcd"

Multiple schemas
  xs:include or xs:import in the schema

IBM 4690 packed numbers
  dfdl:binaryNumberRep "ibm4690Packed"

IBM 4690 packed calendars
  dfdl:binaryCalendarRep "ibm4690Packed"

DFDL Byte Value Entities
  Use of %#r syntax in a DFDL String Literal other than the
  dfdl:fillByte property

DFDL Standard Character Set
Encodings
  dfdl:encoding name begins with "X-DFDL-".

Bit Order - Least Significant
  Bit First
  dfdl:bitOrder with value 'leastSignificantBitFirst'

<table>
<thead>
<tr>
<th>Table 69 Optional DFDL features</th>
</tr>
</thead>
<tbody>
<tr>
<td>In order to provide portability of a DFDL schema, a minimal or extended conforming processor MUST issue warnings about any DFDL properties it does not implement. This warning can simply state that the property is not recognized. (This allows the implementation to simply have no knowledge of properties it does not need for the subset of features it implements.) For example, if the hidden groups feature were not implemented, then the implementation most likely would not recognize the dfdl:hiddenGroupRef property at all. Such an implementation MUST issue a warning that the dfdl:hiddenGroupRef property is not recognized. It is a Schema Definition Error if a DFDL schema uses an optional feature that is not supported by a minimal or extended conforming processor.</td>
</tr>
</tbody>
</table>
24 Security Considerations

All locations MUST be properly initialized before writing to prevent accidental (or purposeful) transmission of data in the unused parts of data formats. Even when a DFDL description does not specify that data must be written to a particular part of the output representation, a defined pattern MUST always be written.

When unparsing data it is a Schema Definition Error if the representation properties that control filling and padding are not defined by the DFDL schema. The DFDL processor MUST fail if they are not defined so that it is certain no region of the output data has unspecified contents.

If regions within a DFDL-described data object are encrypted, then when decrypting them proper means MUST be used to assure secure passage of passwords to the decrypting software. Such means are beyond the scope of the DFDL language specification.

In addition, if encryption passwords/keys are stored in DFDL schema-described data, then proper means MUST be used to assure that the decrypted form of these passwords is not revealed. Such means are beyond the scope of the DFDL language specification.

30 Appendix A: Escape Scheme Use Cases

This appendix gives additional examples of escape schemes and how they affect interpretation of (parsing) or creation of (unparsing) the data stream.

The tables can be interpreted as the physical data column on the right is parsed to obtain the logical data on the left, or the logical data on the left is unparsed to create the physical representation on the right.

</tr>
</tbody>
</table>

Footnote 50: The ‘%’ character needs escaping as part of DFDL syntax when used as a literal character in DFDL properties. It is escaped by doubling it, i.e., preceding it by another ‘%’ character. In this example the dfdl:escapeEscapeCharacter is defined to be a single ‘%’ character in the data stream.

Table 74 Examples of Escape Block with Same Start and End Characters
31 Appendix B: Rationale for Single-Assignment Variables

DFDL is intended to be a description language. That is, the capture of a data format should be as descriptive/declarative as possible.

An additional quite critical goal for DFDL is that it allows high-performance implementations, including use of parallel processing wherever possible.

DFDL contains an expression language with variables for use in creating parameterized DFDL schemas.

However, the way variables can be used in DFDL is quite constrained. Specifically, the variables are single-assignment. This is a form of immutable object (See https://en.wikipedia.org/wiki/Immutable_object).

Single-assignment variables solve a number of problems.

First, they keep the schema more declarative, because the name of a variable represents a value, not a location. Before assignment, the value is not yet known, after the assignment the value is known, but the consumer of the value need only know the name and need not be aware of the mechanism by which it gets its value or when.

Second, single-assignment variables avoid over-constraining the implementation, thereby preserving the potential for high-performance and parallel processing.

Some digression is useful here: Any variable creates a data dependency in order of processing. The part of the schema reading/using the variable's value depends upon the data value coming from the part of the schema providing that value. This kind of data dependency is inherent and inescapable. Values must be created before they can be used.

However, if one considers a variable to be a location that can be assigned repeatedly, then things are more complex because there is not only data dependency on the value (one part of the schema writes the location, another reads that location), but there is dependency in the other direction: one must read the location before it can be used again for the next value. This is usually called anti-dependency. Anti-dependency is the enemy of high-performance and parallel execution. It forces specific and artificial sequential ordering on things that is due to the way variable names are allocated to storage locations.

If variables are single-assignment only, then only data-dependencies exist. Anti-dependencies don't exist, and implementations are free to work in any way consistent with the (inescapable) data dependencies.
32 Appendix C: Processing of DFDL String literals

A DFDL String Literal describes characters or bytes that can appear in the data. The syntax of a DFDL String Literal is described in Section 6.3. This appendix describes how a DFDL String Literal MUST be processed by a DFDL processor.

32.1 Interpreting a DFDL String Literal

A DFDL String literal is a sequence of one or more string literal parts. Each string literal part describes zero or more characters or exactly one byte. To process a DFDL string literal correctly it is necessary to parse it into its string literal parts using the grammar in Table 3 DFDL Character Entity, Character Class Entity, and Byte Value Entity Syntax of Section 6.3.1 DFDL String Literals.

32.2 Recognizing a DFDL String Literal

When parsing, a DFDL processor MUST be able to recognize a DFDL String Literal in the data. The recognition algorithm is used whenever the DFDL processor needs to process a property of type 'DFDL String Literal'.

The recognition algorithm is as follows:

```plaintext
for each DfdlStringLiteralPart
    if this DfdlStringLiteralPart is found in the data at the current offset
        advance the offset by the width of the characters matched
    else
        return false
    end if
end for
return true
```

32.3 Recognizing DFDL String Literal Part

Each type of string literal part and/or the DfdlESEntity is recognised as described in the table below:

<table>
<thead>
<tr>
<th>String Literal Part</th>
<th>Recognition algorithm</th>
</tr>
</thead>
<tbody>
<tr>
<td>LiteralString</td>
<td>The literal string is specifying a sequence of Unicode characters. The string part is recognized if the same Unicode characters are found in the data at the current offset. Implementation note: It is not necessary for either the LiteralString or the data to be encoded using a Unicode encoding. The matching algorithm MUST operate as if the LiteralString and the data were both converted to Unicode before comparison.</td>
</tr>
<tr>
<td>DfdlCharEntity</td>
<td>The entity is specifying a single Unicode character. The recognition algorithm is the same as for a single-character LiteralString.</td>
</tr>
<tr>
<td>ByteValue</td>
<td>The entity is specifying a single raw byte value. The string part is recognized if the literal byte in the data at the current byte offset matches the raw byte value. This entity is specifying a raw byte value and not a character. It is not always safe to interpret the byte value as a character in the component’s encoding.</td>
</tr>
<tr>
<td>DfdlNLEntity</td>
<td>The entity is specifying a newline character or character sequence. The string part is recognized if a newline character sequence is found in the data at the current byte offset: The newline character sequences are defined in Table 5 DFDL Character Class Entities, in Section 6.3.1.2 DFDL Character Entities, Character Class Entities, and Byte Values in String Literals.</td>
</tr>
<tr>
<td>Entity Type</td>
<td>Description</td>
</tr>
<tr>
<td>-------------</td>
<td>-------------</td>
</tr>
<tr>
<td>DfdlWSPEntity</td>
<td>The entity is specifying a single whitespace character. The string part is recognized if one of the whitespace characters is found in the data at the current byte offset. The whitespace characters are defined in Table 5 DFDL Character Class Entities, in Section 6.3.1.2 DFDL Character Entities, Character Class Entities, and Byte Values in String Literals.</td>
</tr>
<tr>
<td>DfdlWSPStarEntity</td>
<td>The entity is specifying zero or more whitespace characters. The string part is recognized when the entire sequence of whitespace characters starting at the current offset has been consumed. The recognition of this entity cannot fail because it can match zero whitespace characters. The recognition algorithm <strong>MUST</strong> be greedy. All possible whitespace characters must be consumed.</td>
</tr>
<tr>
<td>DfdlWSPPPlusEntity</td>
<td>The entity is specifying one or more whitespace characters. The string part is recognized when the entire non-empty sequence of whitespace characters starting at the current offset has been consumed. The recognition algorithm <strong>MUST</strong> be greedy. All possible whitespace characters <strong>MUST</strong> be consumed.</td>
</tr>
<tr>
<td>DfdlESEntity</td>
<td>The entity is specifying an empty string. The string part is recognized if the data available for matching is zero-length. This entity is only allowed in contexts where the available data is constrained by other DFDL properties.</td>
</tr>
</tbody>
</table>

**Table 75 Recognizing DFDL String Literal Part**
33 Appendix D: DFDL Standard Encodings

This appendix provides a specification template for the definition of DFDL standard encodings and defines two such encodings for use in DFDL schemas. These encodings are optional - DFDL implementations are not required to support them to be in conformance with the DFDL specification. However, if implemented, then a conformant DFDL implementation MUST follow the specification in this appendix.

33.1 Purpose

Additional encoding names are needed for several reasons:

1. Incomplete Information: the definitions of IANA [IANA] and CCSID [CCSID] character set encodings are not sufficiently specific about the encoding, omitting important characteristics such as alignment or bit order. An example of this is the encoding X-DFDL-US-ASCII-7-BIT-PACKED, defined herein.

2. Unnamed or Legacy Encodings: There are many legacy encodings that have no IANA or CCSID identifiers. For example, ITA2 [ITA2] is a 5-bit-per character encoding that is very old, yet still has modern uses.

33.2 Conventions

All indexing of positions is 1-based meaning the first position is position 1. Bytes are unsigned integers with values from 0 to 255 (decimal). Hexadecimal numbers have the prefix "0x". Decimal numbers have no prefix when the context is clear and are explicitly labeled with (decimal) to resolve ambiguity.

33.3 Specification Template

A DFDL standard encoding specification SHOULD include:

1. Name: All DFDL standard encoding names begin with the prefix "X-DFDL-". Note that encoding names are not case-sensitive.

2. Translation table: An encoding/decoding algorithm that provides a complete bi-directional mapping between encoded characters and UTF-16 character codes. Many encodings share character code definitions and describe only different ways of representing those values; hence, this section may reference other IANA, CCSID or DFDL standard encoding definitions.

3. Width: Whether the character set is fixed or variable width. If fixed width, the size of a code unit in bits or bytes.

4. Alignment: Alignment and alignment units for a code unit.

5. Byte order: When a code unit consists of more than one byte of data, the byte order of the code units. Note that the dfdl:byteOrder property does not apply to text.

33.4 Encoding X-DFDL-US-ASCII-7-BIT-PACKED

This encoding is used by MIL-STD-2045 [MILSTD2045] and a variety of related binary data standards.

33.4.1 Name

X-DFDL-US-ASCII-7-BIT-PACKED

33.4.2 Translation table

The characters are exactly the 128 US-ASCII characters with the same code unit values.

51 It is anticipated this appendix will be migrated into a separate document to facilitate the addition of new encodings without revising the DFDL specification.
33.4.3 Width
Fixed width. Each code unit is 7-bits wide.
This encoding differs from US-ASCII in that it specifically uses only 7-bits per character within each byte\textsuperscript{52}. A subsequent character or the next data field may begin in the very next bit after a 7-bit character code of this encoding.
Hence, 8 characters fit exactly into 7 bytes of data as no bits are wasted.

33.4.4 Alignment
1 bit. That is, a code unit may begin on any bit boundary.

33.4.5 Byte Order
Not applicable - code units are always smaller than 1 byte.

33.4.6 Example 1
The table below shows how the 8-character string 'UNIT1234' is encoded into 7 bytes, when the bit order is least-significant-bit first.

<table>
<thead>
<tr>
<th>Logical character</th>
<th>7-bit code unit</th>
<th>Bit placement</th>
<th>Byte value</th>
<th>Byte number</th>
</tr>
</thead>
<tbody>
<tr>
<td>U</td>
<td>1010101</td>
<td>×1010101</td>
<td></td>
<td></td>
</tr>
<tr>
<td>N</td>
<td>1001110</td>
<td>0xxxxxx</td>
<td>0x55</td>
<td>1</td>
</tr>
<tr>
<td>I</td>
<td>1001001</td>
<td>01xxxxx</td>
<td>0x67</td>
<td>2</td>
</tr>
<tr>
<td>T</td>
<td>1010100</td>
<td>100xxxx</td>
<td>0x92</td>
<td>3</td>
</tr>
<tr>
<td>1</td>
<td>0110001</td>
<td>0001xxxx</td>
<td>0x1A</td>
<td>4</td>
</tr>
<tr>
<td>2</td>
<td>0110010</td>
<td>1001xxxx</td>
<td>0x93</td>
<td>5</td>
</tr>
<tr>
<td>3</td>
<td>0110011</td>
<td>110011xx</td>
<td>0xCD</td>
<td>6</td>
</tr>
<tr>
<td>4</td>
<td>0110100</td>
<td>0110100x</td>
<td>0x68</td>
<td>7</td>
</tr>
</tbody>
</table>

Table 76: Example of DFDL Standard Encoding X-DFDL-US-ASCII-7-BIT-PACKED
The bits corresponding to the characters are shown in distinct colors below. The characters that each bit contributes to are written below each of the bits and in the corresponding color.

\[
\begin{array}{c}
01010101
ox1010101 \\
01100111 10010010 00011010 10010011 11001101 01101000 \\
\end{array}
\]

Byte -----1-- -----2-- -----3-- -----4-- -----5-- -----6-- -----7--
Char NUUUUUUU IINNNNNN TTTTTTTT 1111TTTT 22222222 33333332 44444443

This kind of data is often better visualized by numbering the bytes in the opposite direction that is right to left, which leads to this presentation:

\[
\begin{array}{c}
01101000 11001101 10010011 00011010 10010010 01100111 01101010 \\
\end{array}
\]

Byte -----7-- -----6-- -----5-- -----4-- -----3-- -----2-- -----1--
Char 44444443 33333332 22222222 1111TTTT TTTTTTTT IINNNNNN NUUUUUUU

\textsuperscript{52} Though US-ASCII contains only 128 characters DFDL assumes the US-ASCII encoding to use one character per 8-bit byte.
In the above, the bits corresponding to each character code unit are more easily recognized, but the characters appear right-to-left (i.e., backward for English).

33.4.7 Example 2

The bits below represent a 3-bit unsigned integer containing value 7, followed by the ASCII string 'ABC' followed by the ASCII DEL character (character code 0x7F). This illustrates a string not beginning on a byte boundary. Again, the bit ordering is least-significant-bit first.

The bits are written in increasing position and place value from right-to-left:

<table>
<thead>
<tr>
<th>DEL</th>
<th>C</th>
<th>B</th>
<th>A</th>
<th>7</th>
</tr>
</thead>
</table>

In the above example, if one numbers the bits from the right, starting with position 1, the character code for 'A' occupies bits 4 to 10. If one divides the data above into bytes with vertical bars one must start on the right to get:

| char: DEL C B A | bits: 01111111 1000011 1000010 1000001 111 | byte: 7F 87 1C 0F | byte pos: 4 3 2 1 |

| char: DEL C B A | bits: 01111111 1000011 1000010 1000001 111 | byte: 7F 87 1C 0F | byte pos: 4 3 2 1 |
33.5 Encoding X-DFDL-US-ASCII-6-BIT-PACKED

This encoding is used by MIL-STD-6016D (See [MILSTD6016]) and a variety of related binary data standards.

33.5.1 Name

X-DFDL-US-ASCII-6-BIT-PACKED

33.5.2 Translation Table

The characters are a subset of the 128 US-ASCII characters. The assignment of numeric code units to the characters is different for some of the characters and the same for others.

The correspondence of ASCII characters to their code point values is given by the table below.

<table>
<thead>
<tr>
<th>Character</th>
<th>Code Point Value (Decimal)</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>@</td>
<td>0</td>
<td>These characters’ code points are the same as the US-ASCII code point, minus 64 (decimal)</td>
</tr>
<tr>
<td>A to Z</td>

</tr>
</tbody>
</table>
Table 77: Translation Table for DFDL Standard Encoding X-DFDL-US-ASCII-6-BIT-PACKED

33.5.3 Width
Fixed width. Each code unit is 6-bits wide. A subsequent character or the next data field may begin in the very next bit after a 6-bit character code of this encoding. Hence, 4 characters fit into 3 bytes of data as no bits are wasted.

33.5.4 Alignment
1 bit. That is, a code unit may begin on any bit boundary.

33.5.5 ByteOrder
Not applicable. Code units are always less than 1 byte in size.

33.5.6 Example 1
The table below shows how the 8 character string '1234' is encoded into 3 bytes. The bit order is least-significant-bit first:

<table>
<thead>
<tr>
<th>Logical character</th>
<th>6-bit code unit</th>
<th>Bit placement</th>
<th>Byte value</th>
<th>Byte number</th>
</tr>
</thead>

\textsuperscript{53} This list is maintained separately from the other references in the specification to facilitate future migration of this material into a separate document.
Appendix E: Glossary of Terms

**Adjacent** - Two addressable units of the input/output stream are adjacent if they are at consecutive positions.

**Addressable Unit** - This is the unit of storage that makes up the input or output stream holding the representation of the data. The units are bits, bytes, or characters.

**Annotation point** - A location within a DFDL schema where DFDL annotation elements are allowed to appear.

**Applicable Properties** - All the DFDL properties that apply to a given type of schema construct. For example, all the DFDL properties that apply to an xs:simpleType.

**Array** - A set of adjacent elements whose XSD element declaration specifies the potential for it to have more than one occurrence (XSD maxOccurs > ‘1’ or ‘unbounded’). Of course, any given array can have any number of element occurrences, including zero elements or exactly 1 element as long as the occurrence constraints are met. If XSD maxOccurs is ‘unbounded’ then there is no constraint to the maximum number of occurrences, though implementations may have implementation-defined maximum capabilities. An optional element (where XSD maxOccurs is ‘1’, and XSD minOccurs is ‘0’) is not considered to be an array as described in this document. Note that a sequence is not to be confused with an array. A sequence is a complex tuple type for an element; the children of a sequence can be of different types. All elements of an array have the same type and if the type is simple, then they have the same information item members except for the value member.

**Array Element** – An element declaration or reference with XSD property maxOccurs > ‘1’ or ‘unbounded’.

**Augmented Infoset** - When unparsing one begins with the DFDL schema and conceptually with the logical DFDL Infoset. As the values of items are filled in by defaulting, and by use of the DFDL outputValueCalc property (including on hidden items), these new item values augment the Infoset. The resulting Infoset is called the augmented Infoset.

**Binary** - There are two meanings for this word depending on context.

- Data is divided into two broad categories of representations, which are text and binary. Hence, binary representation includes any kind of non-text representation.
- Within binary (not text) data, one distinguishes base-10 representations which are called packed decimal, from base-2 representations which are called binary. The common two's-complement representation used for signed integers is a base-2 binary representation.

**Binary Representation** - Of type xs:hexBinary, or of other type with property dfdl:representation 'binary'. Note that type xs:string can never have binary representation.

**Bit Order** - Within a binary integer, if the most-significant bit is assigned bit position 1, then the bit order is most-significant-bit first. If the least-significant bit is assigned bit position 1, then the bit order is least-significant-bit first. When the bit order is most-significant-bit first, then the least-significant bit of byte N is considered to be adjacent to the most-significant bit of byte N+1. When the bit order is least-significant-bit first, then the most-significant bit of byte N is considered to be adjacent to the least-significant bit of byte N+1.

**Bit Position** - The data stream is assumed to be a collection of consecutively numbered unsigned bytes. Each byte is a numeric value from 0 to 255. The bits of a byte are referred to by their numerical significance as the 2n bit, for n from 0 to 7. Hence, the byte value 255 = 27 + 26 + 25 + 24 + 23 + 22 + 21 + 20. The 27-bit is the most-significant bit, and the 20-bit is the least significant bit. The bits within each byte are assigned numbered bit positions 1 to 8 according to the bit order. Given a bit-order, every bit in the data stream has a unique bit position.

**Bit String** - The ordered set of bits from a first bit with bit position N, to bit position N+M is a bit string of length M bits.

**Byte** - The term "byte" refers to an 8-bit octet. Can also refer to an integer with value from 0 to 255 inclusive. Hexadecimal digit pairs are commonly used to illustrate byte values.

**CCSID** - see Coded Character Set Identifier.
**Character** - An ISO10646 [ISO10646] character having a unique character code as its identifier. This concept is independent of font, typeface, size, and style, so 'F', 'F', 'F', are all the same character 'F'.

**Character Code** - The canonical integer used to identify a character in the ISO10646 [ISO10646] standards. This number uniquely identifies the character independently of the various ways it is represented by different character set encodings of the character. For example: The '[' character known in Unicode [Unicode] as LEFT CURLY BRACKET has character code U+007B. In both ASCII and UTF-8 character set encodings the representation of this character is as a single byte code point 0x7B. However, in EBCDIC-based character set encodings the representation of this same character code is the single byte code point 0xC0.

**Character Set** - An abstract set of characters that are assigned (or mapped to) a representation by a particular character set encoding. For most character set encodings their character set is a subset of the Unicode character set.

**Character Set Encoding** - Often abbreviated to just ‘encoding’. A specific representation of a character set as bytes or bits of data. A character set encoding is usually identified by a standard character set encoding name or a recognized alias name, or by a coded character set identifier or CCSID [CCSID]. These identifiers are standardized. The names and aliases are standardized by the IANA [IANA] (where unfortunately, they are called character set names). CCSIDs are an industry standard. Examples of character set encoding names are UTF-8, USASCII, GB2312, ebcdic-cp-it, ISO-8859-5, UTF-16BE, Shift_JIS. There are also additional DFDL standard character set encodings, see **DFDL Standard Encoding**. The DFDL standard also allows for implementation-defined character set encodings to be supported.

**Character Width** - The number of code units or alternatively the number of bytes or bits used to represent a character in a specific character set encoding is called the character width. Encodings are either fixed width (all characters encoded using the same width), or variable-width (different characters are encoded using different widths). For example, the UTF-32 character set encoding has 4-byte character width, whereas USASCII has a 1-byte character width. UTF-8 is variable width, and any specific character in that encoding has width 1, 2, 3, or 4 bytes. See also **Fixed-Width Character Encoding** and **Variable-Width Character Encoding**.

**Code Point** - The integer that identifies a character within a character set encoding. A code point is represented by one or more code units. When a character set is fixed width, then there is no distinction between a code unit and a code point. For Unicode character set encodings, there is no distinction between a character code and a code point. Examples:
- € - character code U+20AC
  - IBM01148 encoding - the code point is 0x9F, and this encoding is fixed width so there is no distinction between the code point 0x9F and the code unit 0x9F that represents the encoded character.
  - UTF-8 encoding - there is no distinction between the character code 0x20AC and the code point 0x20AC. However, it is represented by 3 code units 0xE2 0x82 0xAC

**Code Unit** - When a character set encoding uses differing variable width representations for characters, the units making up these variable width representations are called code units. For example, the UTF-8 encoding uses between 1 and 4 code units to represent characters, and for UTF-8, the individual code units are single bytes. DFDL's interpretation of the UTF-16 encoding is either fixed or variable width. When format property dfdl:utf16Width 'variable' then UTF-16 is variable width and this encoding uses either one or two code units per character, but in this case each individual code unit is a 16-bit value. When a character set is fixed width, then there is no distinction between a code unit and a code point.

**Coded Character Set Identifier (CCSID)** - An alternate identifier of a character set encoding. Originally created by IBM, CCSIDs are a broadly used industry standard. See [CCSID].

**Component** - A construct within a DFDL schema. These constructs include XSD element declarations, type definitions, group definitions, sequence definitions, choice definitions, element references, and group references. DFDL schema annotations are not components of the schema.
rather they appear on components of the schema or on the top-level xs:schema element of a
schema document.

**Content** - The bits of the data stream data that are interpreted when parsing to compute the
logical value of a simple type, and when unparsing are computed from the logical value for
incorporation into the data stream.

**Content Model** – One of 3 kinds of syntactic structure of XSD element declarations. The DFDL
subset of XSD includes only empty, simple, and element-only content models, and not mixed
content (https://www.w3.org/TR/xml/#sec-mixed-content). An XSD element declaration for an
element of complex type containing a xs:sequence element is said to have a sequence in its
content model. (DFDL’s usage is derived from Section 13.3 of [Walmsley]).

**Contiguous** - An element has a contiguous representation if all parts of its representation are
adjacent in the input/output stream. Most simple types have contiguous representations naturally.
Groups containing elements that are themselves contiguous are also considered to have
contiguous representations irrespective of alignment fill or padding of any kind that exists within
the group. Similarly, arrays of elements that are themselves contiguous are also contiguous. An
example of a non-contiguous representation would be a nillable element, where a flag is used to
determine whether the element is nil, and the location of that flag is not adjacent to the value
representation.

**Count** - The number of occurrences of an element.

**Data Stream** - Data where the format is being described by a DFDL schema. Often abbreviated
to just “data” for short. This use of ‘stream’ implies only that there is a numbering scheme that
specifies a unique **bit position** for every bit within the data. This use of ‘stream’ does not imply
anything about whether the data is persistently stored or not, nor does it imply anything about
whether there are sequential or random-access capabilities for access to the data. When parsing,
the data stream may be referred to as the input stream, and when unparsing the output stream.

**DBCS** - See Double-Byte Character Set

**Decimal** - This term is used several different ways distinguished by context:

1. **Base 10.** When data has text representation, a decimal number has base-10 digits.
2. **Type xs:decimal** - a logical type of number that has an integer component and an
   optional base-10 fractional component. This type subsumes all integer types, as they are
   of type xs:decimal but with the further restriction that the fractional part doesn't exist. Note
   that a base-10 fraction has different rounding properties than a base-2 or floating point
   numeric fraction; hence, xs:decimal is the type commonly used to represent
   currency/money in data.
3. **Packed Decimal** - A binary data representation. See separate glossary entry below.

**Defining Annotations** - The annotation elements dfdl:defineFormat, dfdl:defineVariable, and
dfdl:defineEscapeScheme

**Delimiter** - A character or string used to separate, or mark the start and end of, items of data. In
DFDL, dfdl:lengthKind ‘delimited’ scans the data for initiators, separators, and terminators.

**Delimiter scanning** - When parsing, the process of scanning for a specific item in the input data
which either marks the end of an item or the beginning of a subsequent item. Delimiter scanning
also takes into account escape schemes so as to allow the delimiters to appear within data if
properly escaped.

**DFDL** – Data Format Description Language

**DFDL Infoset** - The abstract data structure that must be provided:

- To an invoking application by a DFDL parser when parsing DFDL-described data using a
  DFDL Schema;
- To a DFDL unparsers by an invoking application when generating DFDL-described data
  using a DFDL Schema

**DFDL Processor** - A program that uses DFDL schemas in order to process data described by
them.
**DFDL Schema** - An XML schema containing DFDL annotations to describe data format and using only the DFDL subset of the XSD language. This includes all included and imported schemas taken together. This also includes both the XSD declarations and definitions and the DFDL definitions provided in the top-level DFDL annotations.

**DFDL Standard Encoding** - A character set for which there is no IANA name or CCSID but the name and definition of which DFDL implementations must agree on. See Section 33 Appendix D: DFDL Standard Encodings.

**Double-Byte Character Set (DBCS)** - A character set encoding where each character code consists of one code unit which uses exactly 2 bytes.

**Dynamic extent** - This is a characteristic of the data stream. When parsing data corresponding to a schema component, the collection of bits within the data stream that contain any aspect of the representation of that schema component make up the component’s dynamic extent.

**Dynamic scope** - This is a characteristic of parts of the DFDL schema. When a definition or declaration contains or references another declaration or definition, then the contained definition or declaration is said to be in the dynamic scope of the enclosing one. The important characteristic of dynamic scoping is that it traverses references. When parsing, the dynamic scope of an element declaration includes all definitions and declarations used as part of parsing that element.

**Element** - A part of the data described by an element declaration in the schema and presented as an element information item in the Infoset.

**Encoding** - See Character Set Encoding.

**Explicit Properties** - The explicit properties are the combination of any defined locally on the annotation and any defined by a dfdl:defineFormat annotation referenced by a local dfdl:ref property.

**Fixed-Length Element** - An element of specified length where dfdl:lengthKind is 'explicit' but dfdl:length is not an expression, or dfdl:lengthKind is 'implicit' (of simple type only). Note that choice branches where dfdl:choiceLengthKind is 'explicit' are also referred to as 'fixed-length' but are not necessarily elements.

**Fixed-Width Character Encoding** - A character set encoding where all characters are encoded using a single code unit for their representation. Note that a code unit is not necessarily a single byte. It may be more than one byte, or some number of bits less than a byte. Examples of different fixed widths are:

- 1-byte wide: ASCII, ebcdic-cp-us, iso-8859-1. See also SBCS (Single-Byte Character Set)
- 2-bytes wide: UTF-16 when dfdl:utf16Width is ‘fixed’. See also DBCS (Double-Byte Character Set)
- 4-bytes wide: UTF-32.
- 7-bits wide: X-DFDL-US-ASCII-7-BIT-PACKED\(^\text{54}\).

**Fixed Array Element** - An array element where XSD minOccurs is equal to XSD maxOccurs.

**Format Property** – A DFDL property carried on a DFDL format annotation.

**Framing** - The term used to describe the delimiters, length fields, and other parts of the data stream which are present and may be necessary to determine the length or position of the content of an element.

\(^{54}\) X-DFDL-US-ASCII-7-BIT-PACKED is a DFDL standard encoding, which uses the US-ASCII characters, but each code unit is stored occupying only 7 bits, not a whole 8-bit-byte. DFDL standard encodings are defined in a separate specification. See Section 33 Appendix D: DFDL Standard Encodings.
Implementation-Defined Feature - A feature where the implementation has discretion in how it is performed, and the implementation MUST document how it is performed.

Implementation-Dependent Feature - A feature where the implementation has discretion in how it is performed, but the implementation is not required to document how the feature is performed.

Index - The position of an occurrence in a count, starting at 1.

Infoset – See DFDL Infoset

Item - A DFDL information set consists of a number of information items; or just items for short.

Least-Significant Bit - Often abbreviated to LSB. In a binary integer the least significant bit is the bit having the least place value. Within an 8-bit unsigned byte, the bit with place value $2^0$ (or 1) is the least significant bit.

Length - When discussing data items and their representations, the term 'length' is used to refer to the measure of the size of the representation of an item in units of bits, bytes, or characters. The length of an array is the number of bits, bytes, or characters making up its representation, and has nothing to do with the number of occurrences of the array. Any element occurrence has length. Only array elements and optional elements have numbers of occurrences other than 1.

Lexical scope - In a DFDL Schema document, the lexical scope of any element is the collection of schema declarations, definitions, and annotations contained within the element textually.

Local properties – Local properties are the properties defined on an annotation in either short, attribute or element form

Logical layer - A DFDL Schema with all the DFDL annotations ignored is an ordinary XSD schema. The logical structure described by this XSD is called the DFDL logical layer. The logical layer of a DFDL schema describes the DFDL Infoset of the data format.

Most-Significant Bit - Often abbreviated to MSB. In a binary integer the most significant bit is the bit having the greatest place value. Within an 8-bit unsigned byte, the bit with place value $2^7$ is the most significant bit.

Nibble - 4 bits. A single hexadecimal digit (0 to F) is often referred to as a nibble as it can be represented in exactly 4 bits.

Node - The term Node is a shorter equivalent to Element Information Item of the DFDL Infoset described in Section 4.2.2 Element Information Items.

Non-Representation Property – A format property that is not a representation property, specifically dfdl:ref, dfdl:hiddenGroupRef, dfdl:choiceBranchKey, dfdl:choiceDispatchKey, dfdl:inputValueCalc, dfdl:outputValueCalc. See also representation property.

Occurrence - An instance of an element in the data, or an item in the DFDL Infoset.

Optional Element - An element declaration or reference where XSD minOccurs is equal to zero.

Optional Occurrence - An occurrence with an index greater than XSD minOccurs.

Packed Decimal – A physical representation of a decimal and integer numbers where each digit is packed into one nibble (4 bits) of a byte. There are several variants, some also include a sign nibble, and some include a padding nibble. The term covers all the following enums of the dfdl:binaryNumberRep and dfdl:binaryCalendarRep properties – ‘packed’ (IBM 390 packed), ‘bcd’ (standard binary coded decimals or BCDs) and ‘ibm4690Packed’ (IBM 4690 packed).

Parse - To construct an Infoset from the data stream representation of the data, based on its DFDL format description.

Physical Layer - A DFDL Schema adds DFDL annotations onto an XSD language schema. The annotations describe the physical representation or physical layer of the data. The physical layer of a DFDL schema describes the representation in the data stream.

Point of Uncertainty - A point of uncertainty occurs in the data stream when there is more than one schema component that might occur based on parsing up to that point. These arise from the xs:choice model group, use of optional and array elements with varying numbers of occurrences, use of unordered sequences, and use of sequences with floating elements.
**Representation Property** - A format property that is used to describe a physical characteristic of a component. Such a property applies to one or more grammar regions of the component. See also non-representation property.

**Required Element** - An element declaration or reference where XSD minOccurs is greater than zero.

**Required Occurrence** - An occurrence with an index less than or equal to XSD minOccurs.

**Required Property** – A DFDL property that must have a value. The required properties for each schema component are listed in Appendix G: Property Precedence.

**Resolved Set of Annotations** - When DFDL annotations appear on

1. a simple type definition and the base simple type it references (recursively, if the base simple type also references another base simple type).
2. an element declaration and the simple type definition from (1) it references.
3. an element reference and the global element declaration from (2) it references.
4. a group reference and the global group definition it references.

They are combined, and the resulting set of annotations is referred to as the *resolved set of annotations* for the schema component.

**SBCS** - See Single Byte Character Set

**Scan** – Examine the input data looking for delimiters such as separators and terminators or matches to regular expressions.

**Single-Byte Character Set (SBCS)** - A character set encoding where each character code consists of one code unit which is exactly a single byte (8 bits).

**Schema** – see DFDL Schema.

**Schema Component Designator (SCD)** - A notation for referring to one of the components of a DFDL Schema. This is a W3C Candidate Recommendation (inactive since Jan 2010). See http://www.w3.org/TR/xmlschema-ref. If not finalized, then a future DFDL specification version may define its own SCD syntax.

**Schema Definition Order** – The order that the schema components are defined in a schema document.

**Specified Length** - An item has specified length when dfdl:lengthKind is "implicit" (simple type only), "explicit", or "prefixed".

**Speculative Parsing** – When the parser reaches a point of uncertainty it attempts to parse each option in turn until one is known-to-exist or known-not-to-exist.

**Static Analysis** - A DFDL Implementation can analyze a DFDL schema and determine the presence of many kinds of errors. This is called static analysis, compilation of the schema, or determining the presence of the error *statically*.

**Surrogate Pair** - A Unicode character whose character code value is greater than 0xFFFF can be encoded into variable-width UTF-16BE or UTF-16LE (which are variable-width encodings when the DFDL property dfdl:Utf16Width is ‘variable’). In this case the representation uses two adjacent code units each of which is called a surrogate, and the pair of which is called a surrogate pair.

**Target Length** - When unparsing, the length (in dfdl:lengthUnits) of an item's representation is the target length. The length of the content corresponding to a logical data value in the Infoset may be shorter or longer than the target length, in which case padding or truncation may be necessary to make the logical data content conform to the target length. Rules for when padding and truncation occur, and how they are applied are specific to simple data types and are controlled by a number of DFDL format properties.

**Text** - Consisting of characters in some character set encoding. Normally text data is expected to be human-readable, but many character set encodings contain special control characters that are
not human-readable, but one calls data containing these control characters text anyway. The dfdl:encoding property is required in order to decode/encode the text.

**Text Representation** - Of type xs:string, or of other types (except xs:hexBinary) with property dfdl:representation 'text'. Note that type xs:hexBinary never has text representation. This term specifically refers to the representation of the SimpleContent region being textual.

**Textual** - Of type Text.

**Twos-Complement** - A very common scheme for representing binary integers within data. A positive integer consisting of N bits is represented as its base-2 absolute value. A negative integer is represented as the complement (all bits inverted) of its absolute value plus 1.

**Unicode** - A character set defined by the Unicode Consortium, and standardized at the International Standards Organization (ISO) as ISO10646.

**Unit** - See Addressable Unit.

**Unpadded Length** - This is the length of the content of an item of the Infoset, prior to any filling or padding which might be introduced due to dfdl:lengthKind "prefixed" or dfdl:lengthKind "explicit". It is equal to or smaller than the target length.

**Unparse** - The process of recreating the data representation in a data stream of the Infoset according to its DFDL format description. The terms *marshalling*, and data *serialisation* are sometimes used, but they connote a sequentiality that is not necessarily the case when using DFDL.

**Validity** - A DFDL Infoset is said to be valid with respect to a DFDL schema if each Infoset item is valid with respect to its corresponding DFDL schema component. Validity is about the Infoset and the values it holds. It is independent of the data representation when parsing or unparsing. See Section 9.6 *Validation*, for a list of the specific value checks that are performed when validating a DFDL Infoset against a DFDL schema.

**Variable-Width Character Encoding** - A character set encoding where characters are encoded using one or more code units for their representation depending on which specific character is being encoded. Examples with their ranges of varying width:

- 1 to 4 bytes: UTF-8
- 1 or 2 16-bit code units: UTF-16 when property dfdl:utf16Width is 'variable'
- 1 or 2 bytes: Shift-JIS

**Well-Formed** – A data stream is said to be well-formed with respect to a DFDL schema if a DFDL processor can parse the data into a DFDL Infoset, or there exists a DFDL Infoset such that a DFDL processor can unpars to that data stream. The validity of values in the Infoset is not necessary for data to be well-formed.

**Width** - See Character Width.
35 Appendix F: Specific Errors Classified

This appendix clarifies which errors are Schema Definition Errors and which are Processing Errors.

The following are Processing Errors:

- **Arithmetic Errors**
  - Division by zero
  - Integer Arithmetic Underflow
  - Integer Arithmetic Overflow
  - Note: Floating point math can produce NaN (Not a Number) values. This is not an error, nor are properly typed operations on floating point NaN values.

- **Expression Errors**
  - Dynamic Type Error – unable to convert expression result value to target type
    - Example: non-digits found in string argument to xs:int(…) constructor.
    - Note: if a DFDL Implementation cannot distinguish Dynamic Type Errors from Static Type Errors, then a Dynamic Type Error MUST cause a Schema Definition Error
  - Index out of bounds error – index exceeds the number of occurrences or is less than 1.
    - Note: same error for dfdl:testBit if bitPos is not 1..8, or for character positions in a string-value
  - Indexing of non-array non-optional element
    - Example: x[1] when x is declared and has both XSD minOccurs=“1” and XSD maxOccurs=“1” explicitly, or by not stating either or both of them.
  - Illegal argument value (correct type, illegal value)

- **Parse Errors**
  - Delimiter not found
  - Data from the data stream is not convertible to element type
  - Assertion failed
  - Discriminator failed
  - Required occurrence not found
  - All choice alternatives fail to parse
  - Character set decoding failure and dfdl:encodingErrorPolicy is 'error'

- **Unparse Errors**
  - Truncation scenarios where truncation is being disallowed
  - Rounding error – rounding needed but not allowed. (Unparsing)
  - No choice alternative matching the Infoset can be identified for unparsing.
  - Character set encoding failure and dfdl:encodingErrorPolicy is 'error'

- **Implementation-defined Limit Errors** - Implementations can have fixed or adjustable limits that some formats and some data may exceed at processing time. This specification does not further specify what these errors are, but some possible examples are:
  - Data longer than allowed for representation of a given data type
    - Example: exceed maximum length of representation of xs:decimal when dfdl:representation is "text".
  - Expression references too far back into Infoset (parsing)
  - Expression references too far forward into Infoset (unparsing)
  - Number of array elements exceeds limit.
  - Regular expression exceeds time limit

The following are Schema Definition Errors, regardless of whether they are detected in advance of processing or once processing begins:

- Errors in XML Schema Construction and Structure
  - See XML Schema Specification Part 1, Section 5.1 [XSDLv1]
- Use of XSD constructs outside of DFDL subset
- Implementation-defined Limitations
  - Use of DFDL schema constructs not supported by this implementation.
▪ Example: xs:choice is an optional part of the DFDL specification (see Section 23). If not supported, it MUST be rejected as a Schema Definition Error.
▪ Example: use of packed-decimal when it is not supported by the implementation.
▪ Example: use of dfdl:assert when it is not supported by the implementation (See Spec Section 23 on DFDL Subsets)
▪ Note: Unrecognized DFDL properties or property values can produce a warning and an implementation can attempt to process data despite the warning.
  o Exceeding implementation-dependent limits for schema size/complexity
    ▪ Example: schema too large – simply a limit on how large the schema can be, how many files, how many top-level constructs, etc.
▪ Schema Not Valid
  o See XML Schema Specification Part 1, Section 5.2 [XSDLV1]
▪ UPA violation (Unique Particle Attribution)
▪ Reference to DFDL global definition not found
  o Format definition (dfdl:defineFormat)
  o Escape schema definition (dfdl:defineEscapeScheme)
  o Variable Definition (dfdl:defineVariable)
▪ DFDL Annotations not well-formed or not valid
▪ DFDL Annotations Incompatible
  o E.g., dfdl:assert and dfdl:discriminator at same combined annotation point, or more than one format annotation at an annotation point.
▪ DFDL Properties and their values
  o Property not applicable to DFDL annotation
  o Property value not suitable for property
  o Property conflict
    ▪ Between Element Reference and Element Declaration
    ▪ Between Element Declaration and Simple Type Definition
    ▪ Between Simple Type Definition and Base Simple Type Definition
    ▪ Between Group Reference and Sequence/Choice of Group Definition
  o Required property not found
▪ Expressions
  o Expression syntax error
  o Named child element doesn't exist – E.g., /a/b, and there is no child b in existence.
    ▪ Note: no child possible in the schema is a different error, but also a Schema Definition Error, as /a/b would not have a type in that case.
    ▪ Note: This is a Schema Definition Error, as schema authors are advised to use fn:exists(…) to test for existence of elements when it is possible that they not exist.
  o Variable read but not defined
  o Variable assigned after read
  o Variable assigned more than once
  o Static Type error – type is incorrect for usage
    ▪ Note: if an implementation is unable to distinguish Static Type Errors from Dynamic Type Errors, then both MUST cause Schema Definition Errors.
  o Path step definition not found – e.g., /a/n:b but no definition for n:b as local or global element.
  o Not enough arguments for function
  o Expression value is not single node
    ▪ Most DFDL expression contexts require an expression to identify a single node, not an array (aka sequence of nodes). There are a few exceptions
such as the fn:count(...) function, where the path expression must be to
an array or optional element.
  o Expression value is not array element or optional element.
    ▪ Some DFDL expression contexts require an array or an optional
element.
    ▪ Example: The fn:count(...) function argument must be to an array or
optional element. It is a Schema Definition Error if the argument
expression is otherwise.
• Regular Expressions
  o Syntax error
Appendix G: Property Precedence

36.1 Parsing

The following list gives the order in which DFDL properties are examined when the DFDL parser is positioned at a particular component in the DFDL schema, and about to parse the bitstream modeled by that component.

36.1.1 dfdl:element (simple) and dfdl:simpleType

- Parsing: calculated value (does not apply to dfdl:simpleType or to global elements)
  - dfdl:inputValueCalc
- Parsing: common
  - dfdl:bitOrder
  - dfdl:encoding
    - 'UTF-16' 'UTF-16BE' 'UTF-16LE'
      - dfdl:utf16Width
  - dfdl:encodingErrorPolicy
  - dfdl:ignoreCase
- Parsing: nillable
  - XSD nillable (does not apply to dfdl:simpleType)
    - dfdl:nilKind
      - "literalValue", "logicalValue", "literalCharacter"
        - dfdl:nilValue
- Parsing: occurrences (does not apply to dfdl:simpleType)
  - dfdl:floating
  - (maxOccurs > 1 or unbounded) or (XSD minOccurs = 0 and XSD maxOccurs = 1)
    - dfdl:occursCountKind
      - "expression"
        - dfdl:occursCount
      - "fixed", "implicit"
        - XSD minOccurs
        - XSD maxOccurs
- "parsed"
- "stopValue"
  - dfdl:occursStopValue

- Parsing: identification, framing & extraction
  - dfdl:leadingSkip
    - dfdl:alignmentUnits
  - dfdl:alignment
    - dfdl:alignmentUnits
  - dfdl:initiator
    - dfdl:nilValueDelimiterPolicy (does not apply to dfdl:simpleType)
    - dfdl:emptyValueDelimiterPolicy
  - dfdl:representation "text" or xs:simpleType is 'string'
    - dfdl:lengthKind
      - "implicit"
        - XSD maxLength or dfdl:textBooleanTrueRep/dfdl:textBooleanFalseRep
        - dfdl:lengthUnits
      - "explicit"
        - dfdl:length
        - dfdl:lengthUnits
      - "prefixed"
        - dfdl:prefixLengthType
        - dfdl:prefixIncludesPrefixLength
        - dfdl:lengthUnits
      - "pattern"
        - dfdl:lengthPattern
      - "delimited", "endOfParent"
        - None
  - dfdl:textTrimKind
    - dfdl:textStringPadCharacter, dfdl:textNumberPadCharacter, dfdl:textBooleanPadCharacter or dfdl:textCalendarPadCharacter
▪ dfdl:textStringJustification, dfdl:textNumberJustification, dfdl:textBooleanJustification or dfdl:textCalendarJustification
  ▪ dfdl:escapeSchemeRef
    ○ dfdl:representation "binary" or xs:simpleType is 'hexBinary'
      ▪ dfdl:lengthKind
        ▪ "implicit"
          ▪ XSD maxLength or xs:simpleType
          ▪ dfdl:lengthUnits
        ▪ "explicit"
          ▪ dfdl:length
          ▪ dfdl:lengthUnits
        ▪ "prefixed"
          ▪ dfdl:prefixLengthType
          ▪ dfdl:prefixIncludesPrefixLength
          ▪ dfdl:lengthUnits
        ▪ "delimited", "endOfParent"
          ▪ None
    ○ dfdl:terminator
      ▪ dfdl:nilValueDelimiterPolicy (does not apply to dfdl:simpleType)
      ▪ dfdl:emptyValueDelimiterPolicy
      ▪ dfdl:documentFinalTerminatorCanBeMissing
  ○ dfdl:trailingSkip
    ▪ dfdl:alignmentUnits

▪ Parsing: conversion
  ○ XSD type property
    ▪ "Number"
      ▪ dfdl: decimalSigned
      ▪ dfdl:representation
        ▪ "text"
          ▪ dfdl:textNumberRep
▪ "standard"
  ▪ dfdl:textNumberPattern
  ▪ dfdl:textStandardDecimalSeparator
  ▪ dfdl:textStandardGroupingSeparator
  ▪ dfdl:textStandardExponentRep
  ▪ dfdl:textNumberCheckPolicy
  ▪ dfdl:textStandardInfinityRep
  ▪ dfdl:textStandardNaNRep
  ▪ dfdl:textNumberRounding
    ▪ "explicit"
      ▪ dfdl:textNumberRoundingMode
      ▪ dfdl:textNumberRoundingIncrement
  ▪ dfdl:textStandardZeroRep
  ▪ dfdl:textStandardBase
▪ "zoned"
  ▪ dfdl:textNumberPattern
  ▪ dfdl:textNumberCheckPolicy
  ▪ dfdl:textNumberRounding
    ▪ "explicit"
      ▪ dfdl:textNumberRoundingMode
      ▪ dfdl:textNumberRoundingIncrement
  ▪ dfdl:textZonedSignStyle
▪ "binary"
  ▪ dfdl:byteOrder
  ▪ xs:decimal and restrictions
    ▪ dfdl:binaryNumberRep
      ▪ "packed"
        ▪ dfdl:binaryPackedSignCodes
        ▪ dfdl:binaryDecimalVirtualPoint
• dfdl:binaryNumberCheckPolicy
  ▪ “bcd”, “ibm4690Packed”
  ▪ dfdl:binaryDecimalVirtualPoint
  ▪ dfdl:binaryNumberCheckPolicy
  ▪ “binary”
  ▪ dfdl:binaryDecimalVirtualPoint
  ▪ $xs$:float, $xs$:double
    ▪ dfdl:binaryFloatRep
  ▪ “String”
  ▪ “Calendar”
    ▪ dfdl:representation
      ▪ “text”
        ▪ dfdl:calendarPatternKind
          ▪ “explicit”
            ▪ dfdl:calendarPattern
        ▪ dfdl:calendarCheckPolicy
        ▪ dfdl:calendarTimeZone
        ▪ dfdl:calendarObserveDST
        ▪ dfdl:calendarFirstDayOfWeek
        ▪ dfdl:calendarDaysInFirstWeek
        ▪ dfdl:calendarCenturyStart
        ▪ dfdl:calendarLanguage
      ▪ “binary”
        ▪ dfdl:byteOrder
        ▪ dfdl:binaryCalendarRep
          ▪ “packed”
            ▪ dfdl:packedDecimalSignCodes
            ▪ dfdl:binaryNumberCheckPolicy
            ▪ dfdl:calendarPatternKind
• "explicit"
  ▪ dfdl:calendarPattern
  ▪ dfdl:calendarCheckPolicy
  ▪ dfdl:calendarTimeZone
  ▪ dfdl:calendarObserveDST
  ▪ dfdl:calendarFirstDayOfWeek
  ▪ dfdl:calendarDaysInFirstWeek
  ▪ dfdl:calendarCenturyStart
  ▪ "bcd", "ibm4690Packed"
    ▪ dfdl:binaryNumberCheckPolicy

### 36.1.2 dfdl:element (complex)

- **Parsing: common**
  - dfdl:bitOrder
  - dfdl:encoding
    - 'UTF-16' 'UTF-16BE' 'UTF-16LE'
    - dfdl:utf16Width
  - dfdl:encodingErrorPolicy
  - dfdl:ignoreCase

- **Parsing: nullable**
  - XSD nullable
    - dfdl:nilKind
      - "literalValue"
      - dfdl:nilValue (must be "%ES:")

- **Parsing: occurrences**
  - dfdl:floating
    - (maxOccurs > 1 or unbounded) or (XSD minOccurs = 0 and XSD maxOccurs = 1)
      - dfdl:occursCountKind
        - "expression"
        - dfdl:occursCount
        - "fixed", "implicit"
        - XSD minOccurs
        - XSD maxOccurs
“parsed”

- Parsing: identification, framing & extraction
  - dfdl:leadingSkip
    - dfdl:alignmentUnits
  - dfdl:alignment
    - not "implicit"
      - dfdl:alignmentUnits
  - dfdl:initiator
    - dfdl:nilValueDelimiterPolicy
    - dfdl:emptyValueDelimiterPolicy
  - dfdl:lengthKind
    - "explicit"
      - dfdl:length
      - dfdl:lengthUnits
    - "prefixed"
      - dfdl:prefixLengthType

    - dfdl:documentFinalTerminatorCanBeMissing
  - dfdl:trailingSkip
    - dfdl:alignmentUnits
36.1.3 dfdl:sequence and dfdl:group (when reference is to a sequence)

- Parsing: hidden (xs:sequence only)
  - dfdl:hiddenGroupRef

- Parsing: common
  - dfdl:bitOrder
  - dfdl:encoding
    - 'UTF-16' 'UTF-16BE' 'UTF-16LE'
    - dfdl:utf16Width
  - dfdl:encodingErrorPolicy
  - dfdl:ignoreCase

- Parsing: identification, framing & extraction
  - dfdl:leadingSkip
  - dfdl:alignmentUnits
  - dfdl:alignment
    - not "implicit"
    - dfdl:alignmentUnits
  - dfdl:initiator
  - dfdl:sequenceKind
  - dfdl:initiatedContent
  - dfdl:separator
    - dfdl:separatorPosition
    - dfdl:separatorSuppressionPolicy
  - dfdl:terminator
    - dfdl:documentFinalTerminatorCanBeMissing
  - dfdl:trailingSkip
    - dfdl:alignmentUnits

36.1.4 dfdl:choice and dfdl:group (when reference is to a choice)

- Parsing: common
  - dfdl:bitOrder
- Parsing: identification, framing & extraction
  - dfdl:encoding
    - 'UTF-16' 'UTF-16BE' 'UTF-16LE'
      - dfdl:Utf16Width
  - dfdl:encodingErrorPolicy
  - dfdl:ignoreCase

36.2 Unparsing
The following list gives the order in which DFDL properties are examined when the DFDL unparsers is positioned at a particular component in the DFDL Infoset, and about to unparse and thereby create the bitstream which is the representation of that component.
36.2.1 dfdl:element (simple) and dfdl:simpleType

- **Unparsing: calculated value (does not apply to dfdl:simpleType or to global elements)**
  - dfdl:inputValueCalc (if set then element is ignored)
  - dfdl:outputValueCalc

- **Unparsing: common**
  - dfdl:outputNewLine
  - dfdl:bitOrder
  - dfdl:encoding
    - 'UTF-16' 'UTF-16BE' 'UTF-16LE'
      - dfdl:utf16Width
  - dfdl:encodingErrorPolicy
  - dfdl:fillByte

- **Unparsing: occurrences (does not apply to dfdl:simpleType)**
  - (maxOccurs > 1 or unbounded) or (XSD minOccurs = 0 and XSD maxOccurs = 1)
    - dfdl:occursCountKind
      - "expression"
        - dfdl:occursCount
      - "fixed", "implicit"
        - XSD minOccurs
        - XSD maxOccurs
      - "parsed"
      - "stopValue"
        - dfdl:occursStopValue

- **Unparsing: conversion**
  - dfdl:useNilForDefault (does not apply to dfdl:simpleType)
    - "true"
      - None
    - "false"
      - XSD default or XSD fixed
• XSD nillable (does not apply to dfdl:simpleType)
  • dfdl:nilKind
    ▪ "literalValue", "logicalValue", "literalCharacter"
    ▪ dfdl:nilValue
• XSD type property
  • "Number"
    ▪ dfdl:decimalSigned
    ▪ dfdl:representation
      ▪ "text"
